QUALITATIVE COMPUTER STUDIES OF NEW n-BODY MODELS OF ATOMS AND MOLECULES: PRELIMINARY REPORT

by Donald Greenspan

Abstract

We initiate in this first of a series of papers a new computer oriented approach to the modeling of atoms and molecules. Electron-electron charge interactions are included and several qualitative computations of electron and proton motions are described. The long range goals are to describe electron configurations from nucleon configurations, to develop a viable model of the covalent bond, and to apply the resulting understanding of physical and chemical mechanisms to the study of living cell phenomena.
Qualitative Computer Studies of New n-Body Models of Atoms and Molecules: Preliminary Report

Abstract

We initiate in this first of a series of papers a new computer oriented approach to the modeling of atoms and molecules. Electron-electron charge interactions are included and several qualitative computations of electron and proton motions are described. The long range goals are to describe electron configurations from nucleon configurations, to develop a viable model of the covalent bond, and to apply the resulting understanding of physical and chemical mechanisms to the study of living cell phenomena.
1. **Introduction**

   In our general quest to understand atomic and molecular behavior, and, in consequence, chemical, physical and biological phenomena, quantum mechanics has proved to be superior to all other theories (see, e.g., refs. [1-10, 13-17] and the numerous additional references contained therein). Yet, even this sophisticated mathematical approach has glaring deficiencies, as, for example, those relating to incorrect predictions of molecular bond angles and various nuclear energies [6, 7, 15, 16]. Some of these problems result from the lack of knowledge of nuclear structure and nuclear potentials [7], while others, for example, arise from the simplistic assumption that one-electron orbital results can be extrapolated to larger atoms and to molecules, thereby neglecting electron-electron charge and spin interactions [6, 15]. From the dynamical point of view, the prohibitive number of dimensions required by the quantum mechanical approach, even for the three-body problem [5, 8-10], renders the approach completely impractical for the study of all phenomena which involve the interactions of relatively large numbers of particles [11].

   For all the reasons listed above, we will initiate here a new computer oriented approach to the study of atoms and molecules. Our present examples will be largely qualitative, but will allow for electron-electron charge interactions. Without doubt, we will present many more questions than answers, but those few answers to be given will be most interesting, since our formulation will be completely deterministic and yet possess certain basic characteristics in common with results of quantum mechanics. The enhancement of the present models and possible courses for future research will be discussed in the final section.
2. Mathematical Preliminaries

Let us first give the precise description of an explicit, computer oriented, recursive method for solving an n-body problem. For positive time step $\Delta t$, let $t_k = k \Delta t$, $k = 0, 1, 2, \ldots$. For $i = 1, 2, \ldots, N$, let particle $P_i$ have mass $m_i$ and charge $e_i$, and at time $t_k$ let $P_i$ be located at $\vec{r}_{i,k}$, have velocity $\vec{v}_{i,k}$, and have acceleration $\vec{a}_{i,k}$. Let position, velocity and acceleration be related by the "leap-frog" formulas ([11], p. 107):

\[
\vec{v}_{i,\frac{1}{2}} = \vec{v}_{i,0} + \frac{\Delta t}{2} \vec{a}_{i,0}
\]

\[
\vec{v}_{i,k+\frac{1}{2}} = \vec{v}_{i,k-\frac{1}{2}} + (\Delta t) \vec{a}_{i,k}, \quad k = 1, 2, \ldots
\]

\[
\vec{r}_{i,k+1} = \vec{r}_{i,k} + (\Delta t) \vec{v}_{i,k+\frac{1}{2}}, \quad k = 0, 1, 2, \ldots
\]

If $F_{i,k}$ is the force acting on $P_i$ at time $t_k$, then for the present we assume that force and acceleration are related by

\[
F_{i,k} = m_i \vec{a}_{i,k}
\]

Once an exact structure is given to $F_{i,k}$, then the motion of each particle will be determined recursively and explicitly by (2.1)-(2.4) from prescribed initial data.

The formulation (2.1)-(2.4) is economical, though only approximately conservative. Exact conservation of energy and momentum can be achieved [11], but only through an implicit, less economical approach. Throughout,
in both the two and three dimensional examples to be discussed, the time step to be used in (2.1)-(2.3) will be $\Delta t = 10^{-4}$ and a comprehensive FORTRAN program for implementation of the method is given in the Appendix of [12].

3. **Physical Preliminaries**

   Fundamental to the models to be developed is the question of why the electron in the H atom does not fall into the nucleus. In quantum mechanics, which is strictly a descriptive theory, it is merely shown that electron capture by the nucleus would violate the uncertainty principle, and hence is not consistent with the theory [9]. However, it will be convenient, dynamically, to assume simply that "near" the nuclear surface, the electron is repelled. Thus, in addition to "long range" $\frac{1}{r^2}$ Coulomb attraction, we will allow for "short range" $\frac{1}{r^p}$ repulsion ($p > 2$) between the nucleus and the electron. Indeed, such repulsive forces are known to exist in ionic bonds, with $p$ in the range $9 \leq p \leq 12$ [15, p. 104]. Thus, we assume that the magnitude $F$ of the force $\vec{F}$ between the electron and the nucleus is given by

$$F = \frac{\alpha}{r^2} + \frac{\beta}{r^p}, \quad p > 2,$$

where the parameters $\alpha$ and $\beta$ will be described in the next section.

For electron-electron and proton-proton interactions, we will consider only Coulomb repulsion, which is implemented by setting $\beta = 0$ in (3.1).

4. **A "Hydrogen" Atom**

   Let us begin by considering an atom which consists of exactly one electron and exactly one proton. We will concentrate at present only on its base state, about more which will be stated later, and will model it in a simplistic fashion which is qualitatively similar to the H atom.
Let $P_1$ be the proton and $P_2$ the electron. Choose (3.1) to have the particular form

$$ (4.1) \quad F = \frac{e_1 e_2}{r^2} + \frac{m_1 m_2}{r^p}, \quad p > 2 $$

In analogy with hydrogen, set $m_1 = 1600$, $m_2 = 1$. For computational convenience, set $e_1 = 40$, $e_2 = -40$, since now, independently of $p$, the equilibrium distance between the proton and the electron is unity, because $F = 0$ when $r = 1$. Finally, for later convenience, set $p = 9$, so that (4.1) takes the final form

$$ (4.1) \quad F = -\frac{1600}{r^2} + \frac{1600}{r^9}. $$

Now, the probability that the electron is exactly one unit from the proton and has 0 velocity relative to the proton is zero, so, let us examine the motion of an electron whose distance to the proton is close to unity and whose relative velocity is nonzero. For economy, the discussion of this section is now restricted to two dimensions.

To emphasize the nature of the motion, set $\vec{r}_{1,0} = \vec{v}_{1,0} = 0$, $\vec{r}_{2,0} = (1.1, 0)$, $\vec{v}_{2,0} = (0,4)$, so that the speed of $P_2$ is relatively large. Figure 1 shows the electron motion up to $t = 15000$. This motion is orbital and consists of periodic waves which oscillate about the unit circle with an approximate period of 1.4750 seconds. (Because this paper is largely qualitative, no attempt was made to introduce the de Broglie assumption that each complete orbit consists of an integral number of half-periods). Though Figure 1 emphasizes the nature of the electron's motion in a relatively small computer time, nevertheless, for any $v_{2,0} \neq 0$, the qualitative character of the resulting motion was exactly the same as that shown in Figure 1. The only significant change was in wave periodicity.
Figure 2 shows the electron’s position every 500 time steps up to $t_{176750}$, which is approximately twelve full orbits, for the same initial data as that used for Figure 1. The result is qualitatively analogous to a quantum mechanical electron cloud configuration.

It is perhaps worth noting that, again, because of the qualitative nature of our approach, we will make no special effort at energy analysis, which will be deferred to later papers.

5. A "Hydrogen" Molecule

Before proceeding to the consideration of more complex atoms, let us consider the most simple type of molecule of broad general interest, a "hydrogen type" molecule. We will do this by exploring how two atoms of the type described in Section 4 can unite as a bonded unit. Recall that the radius of the hydrogen atom is 0.53 Å and the distance between the protons of the hydrogen molecule is 0.74 Å. In analogy, then, with hydrogen, itself, we will try to construct our molecule so that the distance between the protons is 1.5, since the radius of the atom described in Section 4 is unity. To do this, begin again with (4.1), allowing $p$ to be a parameter. Let $P_1$ and $P_3$ be protons and $P_2$ and $P_4$ be electrons, as shown in Figure 3, and let the initial data be $x_{1,0} = -0.75$, $y_{1,0} = 0.0$, $x_{2,0} = 0.0$, $y_{2,0} = -0.75$, $x_{3,0} = 0.75$, $y_{3,0} = 0.0$, $x_{4,0} = 0.0$, $y_{4,0} = 0.75$, $v_{i,0,x} = v_{i,0,y} = 0$, $i = 1,2,3,4$. We now vary $p$ from 3 - 11 to see which value then results in a molecular bond. The best such value is $p = 9$, which, incidentally, is why this choice was made in (4.2). For $p = 9$, the electrons and the protons each show only small oscillations in place. The maximum proton oscillation from its initial position was 0.0052, while each electron oscillated exceptionally rapidly with respect to each proton, but only up to a maximum distance 0.0088 from its initial
position. Small perturbations of initial electron positions did not disturb the equilibrium of the molecule. However, larger perturbations of the positions of both electrons, like resetting $P_4$ at $(0.75, -1)$ and $P_3$ at $(-0.75, 1)$ resulted in the dissolution of the molecule, with each separate atom drifting outward. Thus, qualitatively, the addition of a sufficient amount of energy to the molecule will result in its dissolution. Conversely, the formation of the molecule from two suitably situated atoms must result in the release of energy.

The parameter choice $p = 10$ yielded results which were analogous, but not quite as stable as for $p = 9$. All choices other than 9 or 10 in the range $3 \leq p \leq 11$ resulted in an unstable configuration in which the two atoms drifted apart.

We explore next the way in which the molecule forms by bringing two atoms close to each other in a sequence of steps. To do this, let $P_1$ and $P_3$ be the two protons, $P_2$ and $P_4$ the two electrons, and let the initial data be $x_{1,0} = -0.95$, $y_{1,0} = 0$, $x_{2,0} = -0.95$, $y_{2,0} = 1.0$, $x_{3,0} = 0.95$, $y_{3,0} = 0$, $x_{4,0} = 0.95$, $y_{4,0} = -1.0$, $v_{1,0}^{i,x} = v_{1,0}^{i,y} = 0$, $i = 1, 2, 3, 4$. The protons are kept fixed and only the electron motion is observed. This is shown every 500 time steps up to $t_{10000}$ in Figure 4 (a), where, because of the symmetry of the electron motions about the origin, only the motion of $P_2$ is shown. Next, the protons are reset to $(-0.85, 0)$ and $(0.85, 0)$, while the electrons are taken at their final positions in Figure 4 (a), that is, at $(-0.31, 1.02)$ and $(0.31, -1.02)$. All initial velocities are set to $0$ and the electron motions are shown for another 10000 time steps in Figure 4 (b). In Figure 4 (c) are shown electron motions for 10000 time steps after resetting the protons to $(-0.8, 0)$, $(0.8, 0)$, and taking initial electron positions as the terminal ones in Figure 4 (b),
that is (0.12, 0.64) and (-0.12, -0.64). All initial velocities again were reset to \( \vec{0} \). Figure 4 (d) shows 10000 time steps of electron motion after fixing the protons at (-0.75.0), (0.75.0) and the electrons at their final positions in Figure 4 (c), that is, at (-0.15, 0.75) and (0.15, -0.75). All initial velocities were set to \( \vec{0} \). Finally, in Figure 4 (e), the protons were allowed to move freely and the electron motion is shown from their final positions of Figure 4 (d), that is, (0.05, 0.8) and (-0.05, -0.8). After 10000 time steps the new proton positions are shown as the dotted circles in Figure 4 (e).

From Figures 4 (a)-(e), it should be observed that the areas of electron oscillation become increasingly constrained and smaller as the protons move closer to each other. Moreover, the x-coordinates of the electrons are always between the x coordinates of the protons.

Other choices of \( p \) never gave results as satisfactory as those just described. For example, consider, at the lower extreme, \( p = 3 \). A molecule does result when the proton positions are (-1.1,0), (1.1,0) and the electron positions are (0,-1.1), (0,1.1). Small perturbations of the electrons in the Y direction only do not disturb the equilibrium of the molecule, but, invariably, perturbation of electron positions in the X-direction led to dissolution into separate atoms. Computations revealed that such perturbations resulted in electron motions in which the X-coordinates of the electrons exceeded, in absolute value, the X-coordinates of the protons. In such cases, it is indeed unrealistic to say that the \( \frac{1}{r^2} \) component of force is "long range" while the \( \frac{1}{r^3} \) component is "short range", since the orders of magnitudes of these quantities differ only negligibly. Thus, the choice \( p = 9 \) was, in fact, both physically and computationally a realistic one.
6. A "Helium" Atom

In consideration next of an atom which has two protons, new forces must be considered. The exact nature of these forces depends on the particular nuclear model selected, the most popular of which are the liquid-drop, the optical, and the shell models [1,3,4,7,13-15,17]. However, no model yet developed yields a clear and unambiguous description of the forces within the nucleus [7]. For this reason, we will proceed in the following simplistic, qualitative way. Within the nucleus, assume that protons not only repel like $\frac{1}{r^2}$, but that they also attract like $r^q$, $q > -2$, with the net result being nuclear binding [7,15,17]. In particular, let $P_1$, $P_2$ be protons within a nucleus. Let $P_3$, $P_4$ be electrons. As in Section 5, let $m_1 = m_2 = 1600$, $m_3 = m_4 = 1$, $e_1 = e_2 = 40$, $e_3 = e_4 = -40$. Let the force $\vec{F}$ between any proton and any electron have magnitude $F$ given by (4.2), that is by

$$F = \frac{1600}{r^2} + \frac{1600}{r^q}$$

(6.1)

Let the force between the electrons have magnitude

$$F = \frac{1600}{r^2}$$

(6.2)

Finally, let the force between the nuclear protons have magnitude

$$F = \frac{1600}{r^2} - 1600 r^q \quad , \quad q > -2$$

(6.3)

With this formulation, let us study stable configurations of this helium-like atom by varying the parameter $q$. 

Suppose that the average distance between the protons is known, and, for illustrative purposes, let it be 0.4. (Any other choice for this average distance could be treated in a fashion which is completely analogous to that which follows). Consider the initial data $x_{1,0} = 0.2$, $y_{1,0} = 0.0$, $x_{2,0} = -0.2$, $y_{2,0} = 0.0$, $x_{3,0} = 0$, $y_{3,0} = 1.0$, $x_{4,0} = 0$, $y_{4,0} = -1.0$, $\dot{y}_{i,0} = 0$, $i = 1,2,3,4$. Then, for the choices $q = 3,5,6,7,9,12$, only the choice $q = 6$ resulted in each proton oscillating to both sides of its given initial position. Thus, for example, for $q = 3,5$, $P_1$ oscillated in such a fashion that $0 < x_{1,k} \leq 0.2$, for all $k$, while for $q = 7,9,12$, $P_1$ oscillated in such a fashion that $0.2 \leq x_{1,k}$ for all $k$. Thus, the choice $q = 6$ was selected as being physically reasonable for the particular proton configuration selected and the resulting proton and electron motions were completely stable, with each electron's maximum oscillation from its initial position being 0.0017 and each proton's maximum oscillation from its initial position being 0.0028.

To test the stability of the above atom, $P_3$ was reset to $(0.6, 0.8)$. Figure 5 then shows the electron and proton motions up to $t_{10000}$. The electron motion is given every 500 time steps. Though the proton motions are almost negligible, the second electron, by the time $t_{6500}$ has begun a resonant vibration which thereafter continues with the motion of the first electron. The electrons, again, oscillate about a section of a circle which, this time, has a radius which is slightly smaller than the unit circle. Periodic graphing of electron positions is again consistent with the electron cloud concept of quantum mechanics, but in this particular example the motion is limited to that subsection of the cloud for which $-0.6 \leq x \leq 0.6$. 

7. A "Lithium" Atom

Of necessity, we must now turn to three dimensions in order to consider an atom which consists of three electrons and three protons. We continue to avoid those complexities inherent in the existence of spin and of neutrons.

Let us describe first the intuition used in the choice of the initial data. Motivated by the results of Section 6 and desirous of producing greater proton motion than that described in Figure 5, we first set the three protons $P_1$, $P_2$, $P_3$ at the vertices of an equilateral triangle which lies in the $XY$ plane, has side 0.2 units, and has the origin for its centroid. The vertices were taken at $(0, 0.115, 0)$, $(0.1, -0.058, 0)$, $(-0.1, -0.058, 0)$, as shown in Figure 6. Next, the two electrons $P_4$ and $P_5$ were positioned at $(0, 0, 1)$ and $(0, 0, -1)$, which are symmetric with respect to the origin and should be relatively stable choices. Finally, in order to choose what is possibly a relatively stable position for electron $P_6$, we set it equidistant from electrons $P_4$ and $P_5$ and yet relatively close to the protons by choosing its initial position to be $(0, -1.2, 0)$.

With these initial positions, as shown in Figure 6, and with $\dot{0}$ initial velocities, the system was allowed to interact for 200000 time steps. The particles all exhibited planar, oscillatory behavior which is shown every 500 time steps for the time period $t_{175,000}$ to $t_{200000}$ in Figure 7 and is summarized as follows. For $P_1$, $x_{1,k} \equiv z_{1,k} \equiv 0$ while $0.12 \leq y_{1,k} \leq 0.31$. For $P_2$, $z_{2,k} \equiv 0$ while $0.10 \leq x_{2,k} \leq 0.27$ and $-0.15 \leq y_{2,k} \leq -0.06$. The results for $P_3$ are identical with those of $P_2$ except that $-0.27 \leq x_{3,k} \leq -0.10$. For $P_4$, $x_{4,k} \equiv 0$ while $-0.19 \leq y_{4,k} \leq 0.85$ and $0.66 \leq z_{4,k} \leq 1.04$. The results for $P_5$ are identical with those of $P_4$ except that $-1.04 \leq z_{5,k} \leq -0.66$. For $P_6$, $x_{6,k} \equiv z_{6,k} \equiv 0$ while $-1.28 \leq y_{6,k} \leq -0.98$. The centroid
of the system is, to two decimal places, always at the origin. The variation of the distances \( r_{i,k} \) of \( P_i \) to the origin were \( 0.12 \leq r_{1,k} \leq 0.31 \), \( 0.11 \leq r_{2,k} \leq 0.31 \), \( 0.11 \leq r_{3,k} \leq 0.31 \), \( 0.99 \leq r_{4,k} \leq 1.12 \), \( 0.99 \leq r_{5,k} \leq 1.12 \), \( 0.98 \leq r_{6,k} \leq 1.27 \), with the average distances being \( \bar{r}_{1,k} = 0.215 \), \( \bar{r}_{2,k} = 0.210 \), \( \bar{r}_{3,k} = 0.210 \), \( \bar{r}_{4,k} = 1.05 \), \( \bar{r}_{5,k} = 1.05 \), \( \bar{r}_{6,k} = 1.13 \). Thus the third electron \( P_6 \) is, on the average a greater distance from the origin than are the two other electrons \( P_4 \) and \( P_5 \). In quantum mechanical terms one would say that \( P_4 \) and \( P_5 \) are first level electrons while \( P_6 \) is a second level electron. Because of the relatively small numbers involved, it may be also that \( P_1 \) is a second level proton with respect to \( P_2 \) and \( P_3 \), but this is clearly speculative only.

A variety of other calculations led to motions within "electron clouds" which were completely analogous to those described above. This was the case, for example, after resetting \( P_4 \) and \( P_5 \) at (0, 0.4, 0.92) and (0, 0.4, -0.92), respectively, and allowing interaction over 400,000 time steps. However, resetting \( P_6 \) too far from the origin, as was the case for the choice (0, -10.0, 0), resulted in \( P_6 \)'s approaching the origin with such a high speed that it was repelled with a force which eliminated it from all further effective interaction with the system.

8. Remarks

Further computations and modeling beyond that described already were not possible due to the termination of computing funds. In this section, then, let us discuss some of the many interesting questions which remain to be explored.

With regard to the computations already described, each should be repeated using real physical parameters, wherever these are available. Spin should be introduced wherever its existence has been established
experimentally. The presence of neutrons should be explored and, for example, one might examine on the computer possible reasons why $^4\text{He}$ is exceptionally stable why $^5\text{He}$ cannot be made to hold together [7].

With regard to calculations still to be done, computer experimentation with the beryllium atom would be most interesting because of the variety of possible electron, proton, and neutron initial configurations. Also, any eventual computer deduction of the correct bonding angle of the water molecule, i.e., $104.5^\circ$, would be superb. Finally, a computer explanation of the great emphasis which Pauling [16] places on the resonance mechanism in covalent bonding would be of wide interest.

Experimentally, with regard to the simplest atom, hydrogen, it would be of interest to explore the existence of energy states from a constructive, rather than a quantum mechanical descriptive, point of view. The existence of energy states with the well-known [15] electronic orbit radius formula

$$r = 0.5292n^2 \text{Å}, \quad n = 1, 2, \ldots$$

should be examined in a most precise, experimental fashion, to determine whether or not the H-H energy curve has relative extrema or inflections at the values prescribed by (8.1), contrary to the usual smooth curve energy representation.

Finally, it would be of interest to deduce the electron-structure configuration described by quantum mechanics by developing first a new and appropriate theory of nuclear structure. After all, the electrons are relatively free and of exceptionally light mass. They move rapidly and respond readily to the relatively massive, relatively tightly
bound nucleons. It seems plausible, then, that electron arrangement and motion should be deducible in a deterministic fashion from an appropriate theory of the nucleus, an idea which was hinted at in our model of the lithium type atom in Section 7.
