Abstract

Flowback analysis is a powerful technique for debugging programs. It allows the programmer to examine dynamic dependences in a program’s execution history without having to re-execute the program. The goal is to present to the programmer a graphical view of the dynamic program dependences. We are building a system, called PPD, that performs flowback analysis while keeping the execution time overhead low. We also extend the semantics of flowback analysis to parallel programs. This paper describes details of the graphs and algorithms needed to implement efficient flowback analysis for parallel programs.

Execution time overhead is kept low by recording only a small amount of trace during a program’s execution. We use semantic analysis and a technique called incremental tracing to keep the time and space overhead low. As part of the semantic analysis, PPD uses a static program dependence graph structure that reduces the amount of work done at compile time and takes advantage of the dynamic information produced during execution time.

Parallel programs have been accommodated in two ways. First, the flowback dependences can span process boundaries; i.e., the most recent modification to a variable might be traced to a different process than the one that contains the current reference. The static and dynamic program dependence graphs of the individual processes are tied together with synchronization and data dependence information to form complete graphs that represent the entire program. Second, our algorithms will detect potential data race conditions in the access to shared variables. The programmer can be directed to the cause of the race condition.

PPD is currently being implemented for the C programming language on a Sequent Symmetry shared-memory multiprocessor.

Index Terms—debugging, parallel program, flowback analysis, incremental tracing, semantic analysis, program dependence graph.

REVISED

February 2, 1990
1. INTRODUCTION

Debugging is a major step in developing a program since it is rare that a program initially behaves the way the programmer intends. While most programmers have experience debugging sequential programs and have developed satisfactory debugging strategies, debugging parallel programs has proven more difficult. The Parallel Program Debugger (PPD) [28] is a debugging system for parallel programs running on shared-memory multiprocessors (hereafter, called "multiprocessors"). PPD efficiently implements a technique called flowback analysis [6], which provides information on the data and control flow between events in a program’s execution. PPD provides this information while keeping both the execution-time and debug-time overhead low. By using a method called incremental tracing, only a small amount of trace is generated during execution and is supplemented during debugging by detailed information obtained by re-executing only selected parts of the program. PPD is also capable of performing flowback analysis on parallel programs and detecting data races in the interactions between processes. This paper describes the mechanisms used by PPD to efficiently implement flowback analysis for parallel programs. These mechanisms include program dependence graphs and semantic analysis techniques such as interprocedural analysis [2, 11] and data-flow analysis [20].

The goal of PPD is to aid debugging by displaying dynamic program dependences. These dependences should guide the programmer from manifestations of erroneous program behavior (the failure) to the corresponding erroneous program state (the error) to the cause of the problem (the bug). Debugging is a difficult job because the programmer has little guidance in locating bugs. To locate a bug that caused an error, the programmer must reason about the causal relationships between events in the program’s execution. There is usually an interval between when a bug first affects the program behavior and when the programmer notices an error caused by the bug. This interval makes it difficult to precisely locate the bug. The usual method for locating a bug is to execute the program repeatedly, each time placing breakpoints closer to the location of the bug. An easier way to locate a bug is to track the events backward from the error to the point at which the bug caused the error. Flowback analysis tracks events in such a way. The programmer sees, either forward or backward, how information flowed through the program to produce events of interest. Using flowback analysis, the programmer can more easily locate the bugs that led to the observed errors.
Parallel programming offers challenges beyond sequential programming that complicate the problem of debugging. First, it is difficult to order events occurring in parallel programs. The ordering of the events during program execution is crucial for seeing causal relationships between the events (and therefore, the cause of errors). Second, parallel programs are often non-deterministic. Such non-determinism often makes it difficult to re-execute the program for debugging purposes. Third, interactions between cooperating processes in a multiprocessor system are frequent, and these accesses to shared variables can occur without the proper synchronization. PPD not only performs efficient flowback analysis for sequential programs, but also helps address the problems of debugging parallel programs.

In this paper, we address the class of parallel programs that use explicit synchronization primitives (such as semaphores, monitors, or Ada rendezvous) and explicit (and dynamic) process creation. While we are not addressing automatic parallelism, many of our techniques might be extended to such systems. Our current algorithms assume that the underlying machine architecture has a sequentially consistent memory system [26] (as is the case on the Sequent Symmetry). The techniques in this paper are described in terms of the C programming language [21], but they should generalize to other imperative languages. We address a large part of the C language, including primitives for synchronization. We discuss a simple approach to pointer variables but this is a topic that needs further investigation.

This paper is organized as follows. Section 2 presents an overview of the design of PPD. Sections 3 and 4 describe the graph structures and tools used by PPD to perform flowback analysis. Section 3 describes the static program dependence graph, built at compile time, which shows potential dependences between events in the program’s execution. Section 4 describes the dynamic program dependence graph, built at debug time, which shows the actual dependences between events in the execution. Section 4 also describes how dynamic graphs are built by augmenting the static graphs with traces generated during execution and debugging. Section 5 presents the details of incremental tracing. Section 6 describes how flowback analysis is extended to parallel programs and how data races are detected. Section 7 presents some initial performance overhead results.
2. STRUCTURAL AND FUNCTIONAL OVERVIEW

Flowback analysis would be straightforward if we were to trace every event during the execution of a program. However, doing so is expensive in time and space. The user needs traces for only those events that may have led to the detected error. The problem is that there is no way to know what errors will be detected before the execution of the program; either the user has to generate a trace of every event so that the traces will not lack anything important when an error is detected, or the user has to re-execute a modified program that generates the necessary traces after an error is detected. Tracing every event is expensive because of unacceptable overhead, and most often impractical for parallel programs because of the distortions that the debugger would introduce in the interaction pattern between processes. Re-execution is impractical for programs that lack reproducibility, as is often the case with parallel programs.

We use incremental tracing to overcome the above difficulties. The main idea of incremental tracing is to generate coarse-grained traces, called the log, during program execution. Then, during the interactive portion of the debugging session, we use the coarse traces and other compiler-generated information to incrementally produce the fine-grained traces needed to do flowback analysis. This method transfers execution time costs into compile time and debug time. During compile time, we use semantic analyses, such as interprocedural analysis and data flow analysis, to help reduce the amount of information that needs to be generated during program execution. During debug time, we amortize the cost of generating the fine traces over the interactive debugging session. The traces are generated as the programmer asks about dependences in the program.

We divide debugging into three phases: preparatory phase, execution phase, and debugging phase. There are two major components in our debugging system: the Compiler/Linker and the PPD Controller. During the preparatory phase, the Compiler/Linker produces the object code and the files to be used in the debugging phase. While the object code is running in the execution phase, it generates a log to be used in the following debugging phase. When the program halts, due to either an error or user intervention, the debugging phase begins. The PPD Controller oversees the debugging phase, responding to the programmer's requests.
2.1. Preparatory Phase

Figure 2.1 shows the preparatory phase, during which the Compiler/Linker produces, along with the object code, the following:

1) the emulation package that will generate fine traces during the debugging phase to fill the gap between the information contained in the log generated during execution phase and the information needed to do flowback analysis;

2) the static program dependence graph that shows the static (possible) data and control dependences among components of the program; and

3) the program database that contains information on the program text such as the places where a variable is defined or used.

2.2. Execution Phase

The object code plays the major role in the execution phase. Figure 2.2 shows the execution phase, during which the object code generates the normal program output and a log that contains dynamic information about program execution. The log is used, along with the emulation package, during the debugging phase to generate fine traces for the flowback analysis. The log entries include prelogs, which record the values of the variables that might be read before the next logging point, and postlogs, which record the
changes in the program state since the last logging point. The log entries and tracing are described in more detail in Section 5.

2.3. Debugging Phase

The goal of the debugging phase (see Figure 2.3) is to build a graph of the dynamic dependences in a program. The debugging phase assembles information from the previous phases: the static graph and program database generated by the compiler during the preparation phase, and the log generated by the object code during the execution phase. This information is used together with the emulation package to generate the detailed traces needed to build a graph of the dynamic dependences. The PPD Controller oversees the debugging phase. It responds to requests from the programmer, locating the necessary data from the log and static graph, and then executing parts of the emulation package to generate the fine traces.

3. STATIC PROGRAM DEPENDENCE GRAPH

The static program dependence graph (static graph) shows the potential dependences between program components, such as data dependences [23] and branch dependences (similar to control dependences[14]). The static graph is also the basic building block of the dynamic program dependence graph (dynamic graph).

The static graph is a variation of the program dependence graph introduced by Kuck [22]. Since then, there have been numerous variations that can be categorized into two classes according to their applications. First, the program dependence graph is used as an intermediate program representation for the
purpose of optimizing, vectorizing, and parallelizing transformations of the program [14, 22-24, 33]. The main concern in this class is to decide whether there exist any potential dependences between two sets of statements.

Second, the program dependence graph is used to extract *slices* from a program. A slice of a program with respect to variable \( v \) and program point \( p \) is the set of all the statements that might affect the value of \( v \) at \( p \) [35]. Such slices can be used for integrating program variants [18] and for program debugging [14, 31, 34, 35]. One common attribute of the two classes of applications is that they do not use the dynamic information obtained during program execution. However, in PPD, we augment the static graph with the dynamic information obtained during execution and debugging in building the dynamic graph. The dynamic graph in PPD can be viewed as a dynamic slice of the program at an execution point based upon the actual dependences between statements. Accordingly, the static graph structure in PPD differs in
several ways from previous systems.

The structure of the static graph is motivated by the following observations. First, the static graph should contain enough information to build the dynamic graph with only a small amount of trace generated during execution time. A small amount of trace means low execution-time overhead. Second, compile-time efficiency should not be compromised to identify dependences that can be easily determined with dynamic information obtained at execution and debugging times. Since the dynamic trace information effectively unrolls all loops, identifying dependences as loop carried or loop independent [3] at compile time is not necessary to show execution-time dependences. However, this distinction is essential for automatic loop parallelization [1]. Finally, for each subroutine, we want to identify the sets of variables that might be used or defined by the execution of that subroutine. Such identification will allow us to decide whether to show or skip the execution details of a subroutine when showing the dependences requested by the user.

In this section, we describe a static graph consisting of two layers. The outer layer, called the branch dependence graph, shows the branch dependences, and the inner layer, called the data dependence graph, shows the data dependences within the blocks of the branch dependence graph. We will discuss the two layers in detail. Interprocedural analysis is used in building the data dependence graph. With separate compilation, interprocedural analysis also allows us to avoid rebuilding the entire static graph from scratch when one or more modules of the program are modified. The separate compilation issue is described in detail in Section 3.5, where we describe how we use interprocedural analysis in building the static graphs.

3.1. Branch Dependence Graph

The branch dependence graph consists of nodes called control blocks and branch dependence edges between these nodes. Figure 3.1 shows an example branch dependence graph. Such a graph is constructed for each subroutine in the program. A leaf control block represents a block of statements in which the flow of control always enters at the beginning, and that is devoid of conditional or loop control statements. The execution order of the statements in a leaf control block is therefore strictly sequential, representing a basic block. For programs without goto statements, the branch dependence graph is identical to the control dependence graph described by Ferrante, et al [14]. We describe how goto statements affect the structure of the static and dynamic graphs in Section 4.3.
extern int g1, g2, g3;
extern int A[100], B[100];
Wolf () {
    int i, j, k, l, a, b;
    s1: if (g1 > 0) {
        a = Add2(g1, g2);
    } else {
        s2: g1 = 0;
        s3: SubY();
        s4: a = g1;
        s5: L1:
        s6: a = (A[i] = b);
        s7: b = A[j];
        s8: A[k] = B[l] + a + b;
        s9: H:
        s10: a = g1;
        s11: g2 = a;
        s12: SubX(a);
        s13: g2 = g2 + g3;
        s14: while (a > 1) {
            a = a - 1;
            s15: g2 = g2 * a;
        }
    }
}; /* Wolf */

Figure 3.1. A Sample Static Graph

There are four non-leaf block types needed for C programs. The first type represents conditional statements, such as if or switch, in which only one of the immediate descendent blocks will be executed. Block A in Figure 3.1 is of this type. During execution, either block C or block D will be executed. The second non-leaf block type represents loop control statements such as while or for. Execution of the descendent blocks may be repeated zero or more times depending upon the loop control statement. Block B in Figure 3.1 is of this second type.
The third and fourth non-leaf block types do not correspond to any statement. The third type acts as summarizing block for its descendent blocks and is used when its descendents constitute an e-block; an e-block is the unit of incremental tracing during debugging (described in Section 5.1). All the descendents of a summarizing block execute in left-to-right order. Also, the root block of a static graph is a summarizing block, even if we do not construct an e-block out of the subroutine.

The fourth type of non-leaf block is a dummy block. This block exists only as a descendent of a conditional block to group together the blocks (if there are more than one) dependent on the conditional. The dummy block satisfies the condition that only one of the descendents of a conditional block will be executed. All the descendents of a dummy block will also be executed in left-to-right order. Control block D in Figure 3.1 is a dummy block with three descendents. Leaf blocks G and H are defined because of labels "L1" and "L2"; flow of control can potentially enter at these points. (We introduced these labels to show how labels affect the static graph, although there is no goto statement in the example program.)

Associated with each control block (except dummy blocks) are four sets of variables — the USED, DEFINED, GUSED, and GDEFINED sets — and a data dependence graph. The USED set is the set of variables that might be referenced before they are defined by a statement in this block; it is the set of upwardly-exposed used variables [2] of this block. The DEFINED set is the set of variables whose values might be defined by statements in this block. The GUSED set is the set of variables that might be used before they are defined in this block or any block in a subroutine called from this block (following the transitive closure of calls). The GDEFINED set is similarly defined. While the USED and DEFINED sets are determined locally by inspecting the statements belonging to a block, the GUSED and GDEFINED sets can only be determined by interprocedural analysis. The GUSED and GDEFINED sets are described in more detail in Section 3.5 on interprocedural analysis.

The branch dependence graph for a subroutine can have several summarizing blocks, one for each e-block in the subroutine. The four sets (the USED, DEFINED, GUSED, and GDEFINED sets) for a summarizing block are the unions of the same sets of all the descendents blocks that constitute the e-block.

---

† We overload the use of USED, GUSED, DEFINED, and GDEFINED. For example, we can say GUSED(P) for a subroutine P and GUSED(B) for a control block B.

‡ There is a correspondence between the terminology that we use[10,28] and the terminology used by Banning[7] as follows: our "DEFINED" corresponds to Banning's "IMOD", USED to IUSE, GDEFINED to MOD, and GUSED to USE.
However they do not contain variables that cannot be accessed outside of the corresponding e-block. For example, those four sets for a subroutine do not contain variables local to the subroutine. The program database [28] contains the scope information of each variable, telling whether a given variable is a global variable, a variable local to a subroutine, a static variable (in C), or a formal parameter of a subroutine. It also tells whether a given global variable of a parallel program is a shared variable. (Sequent C has two additional key words to support parallel programming: shared and private.) The variables in the USED and DEFINED sets of the summarizing block are the variables that will be written to the log (described in Section 5) at execution time.

The structure of the branch dependence graph and the four sets of used and defined variables allow for easy identification of the sets of variables that might be used and defined during the execution of an e-block. They also allow for easy identification of which e-blocks might use or modify a given variable. Section 5 discusses how these data structures work together with the log and incremental tracing.

3.2. Data Dependence Graph

Each control block (except for summarizing and dummy blocks) has a data dependence graph that shows the dependences between statements belonging to that block. Figure 3.2 shows a sample control block and its data dependence graph. The (static) data dependence graph has two node types: singular and sub-graph nodes. The singular node represents an assignment statement, a control predicate in a statement such as an if or switch, or branch statement such as goto or exit. For a constant used on the right-hand side of a statement, we create a constant node, which is a sub-type of the singular node. The sub-graph node represents the call site of a subroutine and is a way of encapsulating the inside details of such subroutines. There is one static graph for each subroutine. Each node of the data dependence graph is labeled with the statement number and either an identifier or an expression.

The data dependence graph has three edge types: data dependence, flow, and linking edges. The data dependence edge represents a true dependence [3,23]. (A statement \( S_2 \) has a true dependence upon another statement \( S_1 \), if \( S_2 \) uses output of \( S_1 \).) A flow edge from \( n_i \) to \( n_j \) is defined when the event represented by \( n_j \) immediately follows the event represented by \( n_i \) during execution; it shows the control flow of the program. The linking edge helps resolve the dependences that can only be determined during
\[ s15: \quad a = a - 1; \\
\]
\[ s16: \quad g2 = g2 \times a; \]

\( U: \text{USED} \)
\( D: \text{DEFINED} \)

: data dependence edge

: singular node

**Figure 3.2. Basic Block and Its Data Dependence Graph**
*(Block E in Figure 3.1)*

execution time, for example, deciding which array element is actually accessed when the array index is a variable. Linking edges are described in more detail in Section 3.4.

The top of the control block shows the variables in the \text{USED} set of the block and the bottom of the block shows the variables in the \text{DEFINED} set of the block. A data dependence edge from the \text{USED} entry for a variable into a node \( N \) shows a *dangling* data dependence in this block — meaning that the value of the variable has not been defined in this block before the statement represented by node \( N \). A data dependence edge into the \text{DEFINED} entry for a variable shows the last statement in the block that modifies the variable. All the nodes in a data dependence graph are totally ordered according to the corresponding statements in the control block, because statements in a control block are sequential. This total ordering of nodes is represented by the flow edges connecting these nodes in a control block, so we can say that a node is after or before another node in a control block. We will not explicitly show the flow edges in the figures in this section.

Inter-block dependences (dependences between two statements belonging to different control blocks) are not resolved during compile time; they are not recorded in the static graph. Inter-block dependences are resolved during debugging and are recorded in the dynamic graph (described in Section 4).
3.3. Parameters to Subroutines

To map between formal parameters and actual parameters of a subroutine call during debugging, we create a parameter node (a variant of the singular node) for each actual parameter passed to a subroutine. Each parameter node is labeled with "%" followed by the parameter position (%0 represents a function return value). Figure 3.3 shows the static graph of control block C in Figure 3.1 and shows how actual parameters are mapped to the formal parameters of a called subroutine.

3.4. Arrays and Linking Edges

Array index values are usually unknown during compile time, so it is not possible to identify the array elements that will actually be accessed. Our approach is to supply enough information in the static graph so that array reference dependences can be quickly determined at debug time. We use a new edge type, the linking edge, and two variants of the singular node, the index and select nodes. Index nodes show the indices used in array accesses, and select nodes represent read-accesses of an array. Linking edges represent potential data dependences, and are used during debugging to quickly locate the actual dependences.
s6: \( a = (A[i] = b); \)
s7: \( b = A[j]; \)
s8: \( A[k] = B[l] + a + b; \)

\[7: \text{USED} \]
\[8: \text{DEFINED} \]

\[ \rightarrow : \text{data dependence edge} \]
\[ \cdots \rightarrow : \text{linking edge} \]

Figure 3.4. Data Dependence Graph with Array and Linking Edges
(Control Block G in Figure 3.1)

To represent an assignment to an array element, a singular node is created. Nodes "s6:A" and "s8:A" in Figure 3.4 are examples of such nodes. As with assignments to scalar variables, this node contains data dependence edges from the nodes representing the variables used in the right-hand side of the assignment. However, for array assignments, a linking edge is then added, from the most recent node in the control block that writes the same array, to the assignment node. If there are no previous writes to the same array in the control block, then a special USED set entry is made for the array and a linking edge is added from this entry. Finally, an index node is created for each array index and is labeled with "%" followed by the index position (similar to a parameter node). A data dependence edge is added from each index node to the assignment node. For example, node "s6:A" in Figure 3.4 contains three incoming edges: one data dependence edge for the index value, one data dependence edge for the variable used in the
right-hand side of the assignment, and a linking edge from the USED set entry for the array being modified (since there were no previous modifications of array "A" in the control block).

A read from an array element is handled identically except that a select node is created to represent the read. For example, the select node above node "s7:B" in Figure 3.4 represents the array access "A[j]" on the right-hand side of statement s7. This select node has an incoming data dependence edge from the index node and an incoming linking edge from node "s6:A", the most recent modification of array "A" in the control block. The above mechanisms are similar to the ideas used for array related dependences in [31].

The actual data dependences for each array read are determined during debugging and are reflected in the dynamic graph. Once the fine traces for the e-block containing an array read are generated, the index values of all array accesses in that e-block will be known. The linking edges are followed backwards, from the select node, until an assignment to the same array location is found. A data dependence edge can then be added in the dynamic graph from this assignment to the select node. If no such assignment is found (the USED set entry for the array was reached), then a dangling dependence exists for the array read. The dangling dependence can then be resolved as described in Section 5.

3.5. Interprocedural Analysis and Data Dependence Graph

GUSED and GDEFINED sets, computed by interprocedural analysis, allow us to identify more precise (potential) dependence information than the worst-case assumption that every global variable in the program is possibly used and defined by each call to a subroutine. In this section, we describe the use of the GUSED and GDEFINED sets.

Building the data dependence graphs with interprocedural analysis is done in two steps. The first step is done at compile time without interprocedural information, building the pre-graph form of the data dependence graphs. The graphs in Figures 3.2–3.4 are all pre-graphs. The second step is done at link time, producing the post-graphs by modifying (if necessary) the pre-graphs with interprocedural summary information. When several modules of a program are re-compiled with separate compilation, we need to rebuild only the pre-graphs of the re-compiled modules. Only those post-graphs that contain calls to subroutines whose GUSED or GDEFINED set has changed need to be built again. Figure 3.5 shows the pre-
graph and the post-graph for control block H in Figure 3.1. We outline how to build the pre-graph and the post-graph in this section. Detailed algorithms for building these graphs appear in [9].

Our approach (heuristics) to include interprocedural information is as follows. When we meet a subroutine call in building the pre-graph of a control block, we assume that all the global variables written so far in the control block might be written by the subroutine. Then, we create a linking edge for each such global variable out of the most recent node that wrote the variable, and into the sub-graph node representing the subroutine call. We use the linking edges to identify the parts of the pre-graph that might need to
be modified to produce the corresponding post-graph.

When building the post-graph, the interprocedural summary information is reflected in each sub-graph node in the following ways: First, we create a data dependence edge into the sub-graph node for each global variable that is in the GUSED set of the sub-graph node. Second, we create a data dependence edge out of the sub-graph node for each global variable that is in the GDEFINED set of the sub-graph node. Finally, we create a linking edge into the sub-graph node for each global variable that is in the GDEFINED set but is not in the GUSED set of the sub-graph node.

The linking edge is needed because GUSED and GDEFINED are sets of variables that might be accessed during the procedure call. For example, if during debugging we discover that "SubX" (see Figure 3.5) does not actually modify "g1", we need to locate the most recent node before "SubX" that modifies (or might modify) "g1", which in this example is "sI1:g1". The linking edge from "sI1:g1" to "sI2:SubX" serves this purpose. (Note that the linking edge was similarly used in the previous subsection for arrays.)

Figure 3.5 shows how the post-graph is constructed from the pre-graph and information from interprocedural analysis. First, the linking edge of "g2" into the sub-graph node in the pre-graph is changed into a data dependence edge, because "g2" is in GUSED(SubX). Second, the data dependence edge of "g2" out of the sub-graph node into the node "sI3:g2" is disconnected from the sub-graph node and reconnected into the node "sI0:g2", because "g2" is not in GDEFINED(SubX). The reconnection is done by following the "g2" dependences through the sub-graph node. Third, there are two additional edges out of the sub-graph node: one into the GDEFINED entry for "g3" and the other into node "sI3:g2". These edges are added because "g3" turned out to be in GDEFINED(SubX). Last, the data dependence edge from the USED entry for "g3" into node "sI3:g2" is deleted. The linking edge out of "sI1:g1" into the sub-graph node is intact because "g1" is in GDEFINED(SubX) but is not in GUSED(SubX).

3.6. Pointers and Parameter Aliases

Pointers and aliases make the semantic analysis of the program difficult. Currently, we do not detect dependences involving pointers at compile time. Instead, we simply trace all uses of pointers in the log and
establish such dependencies during debugging. This approach will be viable if the dynamic frequency of pointer references is low. For example, tracing a pointer access requires approximately 20 assembly language instructions, and if one out of every ten instructions is a pointer reference [29], the tracing will slow execution by a factor of three. However, we are investigating ways to reduce the potentially large amount of execution-time traces due to pointers and dynamic objects by using a method similar to [19, 27].

Our methods can be extended to handle the special case of aliases resulting from reference parameters in languages like Pascal or FORTRAN. Our approach is to identify, at compile time, potential aliases resulting from reference parameters [7, 8]. In the static data dependence graphs, we link together (with linking edges) all nodes representing writes to variables that are potential aliases. In the prolog for a sub-routine containing reference parameters that are potential aliases, the address of each such reference parameter is recorded. Then, during debugging, aliases can be detected by comparing these addresses. Parameters whose addresses are the same are aliases. In addition, a parameter whose address is identical to the address of a global variable is an alias for that variable. Once aliases are known, incremental tracing can be employed, and actual data dependences can be established in the dynamic graph (by following linking edges back, as was done for arrays).

4. DYNAMIC PROGRAM DEPENDENCE GRAPH

The dynamic program dependence graph (dynamic graph) is constructed during debugging to show the causal relations between events in a program's execution. This graph shows the dynamic data and branch dependences exhibited by the execution. In this section, we describe how the dynamic graph is constructed from the static graphs (generated at compile time) and the fine traces (generated by incremental tracing during debugging), and illustrate its construction with an example.

4.1. Dynamic Program Dependence Graph

A dynamic graph is constructed for each e-block executed during the program's execution, and shows the actual dependences that occurred among events belonging to that e-block. The dynamic graph is constructed by splicing together the data dependence graphs for each control block that was executed in the e-block. Data dependence edges are added between the graphs to show the dynamic data dependences that actually occurred, and branch dependence edges are added to show how control flow was transferred from
one control block to another. In addition, ENTRY and EXIT nodes are added to show the entry and exit points of the e-block.

Singular nodes are augmented with values (when appropriate) indicating the value computed by the statement represented by the node. Sub-graph nodes, which encapsulate the execution details of subroutine call, can be expanded to uncover a nested dynamic graph showing the details of the call.

A flow edge from \( n_i \) to \( n_j \) is defined when the event represented by \( n_j \) immediately follows the event represented by \( n_i \) during execution; it shows the control flow of the program. A data dependence edge shows a true data dependence between two nodes.

A branch dependence edge from \( n_i \) to \( n_j \) is defined when the event represented by \( n_i \) is the most recent branch statement, such as an if or goto statement (of the event represented by \( n_j \)) that caused the program control to flow to \( n_j \) in a given execution instance. The branch dependence is concerned about the actual program control flow in an execution instance of a program, while control dependence in Program Dependence Graphs (PDG) [14] is concerned about the potential program control flow in a program. More details on branch dependences and their relationship to control dependences are presented in Section 4.3.

A synchronization edge shows the initiation and termination of synchronization events between processes, such as semaphore operations or sending and receiving messages. Synchronization edges are used in debugging parallel programs and will be described in more detail in Section 6.

4.2. Building the Dynamic Graph

We will use subroutine “Wolf” to illustrate how the dynamic graph is built from the static graph and fine traces. The data dependence graphs for the blocks A and B are given in Figure 4.1, and the graphs for the remaining blocks were given back in Figures 3.2–3.5. We assume that, of the choice between blocks C and D, block C is executed. We also assume, for this execution instance, the execution sequence of blocks is: A, C, B, E, B, E, B — i.e., we assume the body of the while statement (blocks B and E) is executed twice.

Figure 4.2 shows the resulting dynamic graph of this execution. (Boxes showing blocks are not part of the dynamic graph.) Notice that for simplicity, parameter nodes for simple variable parameters are
replaced in the figure with labeled edges. Also, flow and synchronization edges are not shown. The graph was constructed by combining the data dependence graphs in the order that their control blocks were executed, and by inserting branch and data dependence edges between them. To insert the data dependence edges, we connect each variable in the GUSEED set to the variable in the most recent GDEFINED set that contains the variable. The branch dependence edges are obtained from the branch dependence graph.

The linking edges in the static graphs are the means of representing data dependences unresolved during compile/link time. The linking edges that connect nodes that write to the same array will not be included in the dynamic graphs. Also, a linking edge going into a select node for a read from an array element will be replaced with a data dependence edge coming out of the most recent node for a write to that same array element.

A linking edge coming out of a variable and going into a sub-graph node is deleted or replaced with a data dependence edge, depending on the execution of the sub-graph node. If the variable is actually written by the sub-graph node, we simply delete the linking edge. If it is not written, we delete the linking edge and make the data dependence edges of the variable that are coming out of the subgraph node bypass the sub-graph node in the dynamic graph. These data dependence edges will be now coming from the node from which the deleted linking edge originally came (note that if the variable is read in the sub-graph node before it is written, there would have never been a linking edge; it would be a data dependence edge). In
addition, as more is learned as the debugging session proceeds about which variables are actually read and written inside sub-graph nodes, data dependence edges may have to be re-routed to keep the dynamic graph up-to-date. For example, if it is discovered that the execution represented by a sub-graph node did not actually modify a variable that is in its GDEFINED set, then the data dependence edge for that variable would be re-routed around the sub-graph node.
For example in the post-graph of Figure 3.5, if the execution of "SubX" actually wrote "g1", the linking edge coming out of node "s1: g1" and going into the sub-graph node would be deleted in the dynamic graph. If the execution of "SubX" did not write "g1", the linking edge would be replaced with a data dependence edge that bypasses the sub-graph node and goes into the GDEFINED entry for "g1". The data dependence edge coming out of "s2: SubX" and going into the GDEFINED entry for "g1" would also be deleted in this case.

4.3. Dynamic Graph and goto Statements

Goto statements affect the process of building the dynamic branch dependence graph. We will use the example program segment in Figure 4.3 to first show how goto statements affect the dynamic branch dependence graph. We then compare this form of the graph to one based on control dependences used in

```
if (C0) {
    if (C1) {
        if (C2) {
            a = b;
            goto L1;
        } else {
            if (c3) {
                b = c;
                goto L1;
            } else {
                L1:
                c = d;
            }
            d = e;
        } else {
            a = c;
        };
    }
    d = c;
};
```

Figure 4.3. A Sample Program Segment with goto Statements
the PDG by Ferrante, et al [14].

There are three ways program control can flow from a basic block (*source block*) to another basic block (*target block*): the execution of a conditional branch statement, the execution of an un-conditional branch statement (such as a *goto* statement), or the execution falling through from the source block to the target block.

In the first and second cases, a branch dependence edge is constructed from the node representing the branch statement to the target block. In the third case, a branch dependence edge is constructed depending upon how control flow arrived at the target block. Since control flow fell through to the target block, its parent is a dummy node, which is a child of a node representing a conditional statement or loop (such as *while* or *if*). If the value of the conditional expression caused control flow to reach the children of the dummy node (which includes the target block), then the target block has a branch dependence on the conditional expression. Otherwise, the target block was reached only because the most recently executed *goto* jumped into a block, which then fell through to the target block. In this case, a branch dependence edge is constructed from this *goto* to the target block.

Figure 4.4A shows the static and dynamic branch dependence graphs for the program segment in Figure 4.3 in which execution sequence of blocks is C0, C1, C2, B1, B3, B4, B6. Note that B3 has a dynamic branch dependence edge from the *goto* statement of B1, while B3 has a static branch dependence edge from C3; the dynamic branch dependence graph shows that control flow reached B3 through C2 and B1 (not C3) in this execution instance. Control flow fell through from B3 to B4, but since C2 evaluated to true, none of the children of C2's dummy node (which includes B4) would have been executed were it not for the *goto* statement in B1. B4 therefore has a dynamic branch dependence edge from this *goto* statement. Control flow fell through from B4 to B6, but since C0 evaluated to true, the children of its dummy node were all executed, so B6 has a dynamic branch dependence edge from C0 (and not from the *goto* statement of B1).

The PDG by Ferrante, et al [14] uses a somewhat different notion of dependences for *goto* states. Figure 4.4B shows the (static) control dependence subgraph for their PDG (of the program segment in Fig-
Figure 4.4. Branch and Control Dependence Graphs

Figure 4.4) and the corresponding (possible) dynamic control dependence subgraph.† Note that B3 is a post-dominator of C2. The PDG represents this relationship by showing a control dependence for B3 from C1, not from the goto statement of B1: the PDG does not show how control actually flowed to a given point during execution. The (dynamic) branch dependence graph in Figure 4.4A is better suited to show the causality of program events than the graph in Figure 4.4B, because it shows how control actually flowed to a given point during execution. However, the dynamic control dependence subgraph in Figure 4.4B combined with that in Figure 4.4A, might be informative to show the possible behavior of the program in some other execution instances.

† They do not actually build a dynamic graph.
5. INCREMENTAL TRACING

We use incremental tracing to reduce the execution overhead associated with flowback analysis. In incremental tracing, we divide the program into blocks, called emulation blocks (e-blocks), and generate coarse execution-time traces (logs) based on these blocks. For parallel programs, there is one log file for each process created during the execution. During the interactive portion of the debugging session, we use these traces and other compiler-generated information to incrementally produce the fine-grained traces needed to do flowback analysis. In this section, we first describe the compile time issues associated with dividing the program into e-blocks. We also describe the debugging time issues associated with how to quickly locate the coarse traces generated by a particular execution instance of an e-block. Accesses to large arrays pose a special problem in controlling execution overhead, since generating traces that contain the entire contents of an array could substantially slow a program's execution. Section 5.5 addresses this issue and presents heuristics to deal with the problem. Section 7 discusses the effectiveness of these heuristics.

5.1. Emulation Blocks and Logs

As described in Section 2, the traces generated during program execution include prelogs and postlogs. The object code generated by the compiler/linker during the preparation phase contains code to generate the prelogs and postlogs. By using semantic analysis, we divide the program into numerous segments of code called e-blocks. Each e-block starts with code to generate a prelog and ends with code to generate a postlog. The USED and DEFINED sets of an e-block correspond to its prelog and postlog. An e-block is also the unit of incremental tracing during debugging. As will be described in more detail later in this section, a subroutine is a good example of an e-block.

The i'th prelog and the corresponding postlog generated by an e-block during program execution are called prelog(i) and postlog(i), respectively. The time interval between a prelog and its matching postlog is called a log interval and is denoted as I_i for the log interval between prelog(i) and postlog(i). Programs usually contain loops, so a given e-block in a program may have several corresponding log intervals during execution. Figure 5.1 shows example log intervals.
Prelog(i) consists of the values of the variables belonging to the USED set (of the e-block that generated the prelog) at the beginning of $I_i$, and postlog(i) consists of the values of the variables belonging to the DEFINED set (of the same e-block) at the end of $I_i$. Each log entry also carries the e-block identifier that generated the log entry. To reproduce the same program behavior for log interval $I_i$ during the debugging phase, we use the program code for the e-block that generated prelog(i) and postlog(i), the log entries generated during $I_i$, and the same input as originally fed to the program during that log interval.

Log intervals nest when one subroutine calls another. For example, in Figure 5.1 we assume that log interval $I_3$ corresponds to the execution of a subroutine named Sub3. We also assume that $I_4$ corresponds to the execution of a subroutine named Sub4, that is called from within Sub3. Prelog(3) and postlog(3) are made at the start and end of $I_3$, respectively; prelog(4) and postlog(4) are made at the start and end of $I_4$, respectively. In this case, we say log interval $I_4$ is nested inside log interval $I_3$. When we need to generate fine traces at debugging time for log interval $I_3$, we can use postlog(4) to avoid generating fine traces for $I_4$; we update the program state with postlog(4) when the call to Sub4 is reached, and skip over the execution of Sub4. Details on the fine trace generation and debugging time activities are given in [28].

5.2. Tradeoffs for Constructing E-blocks

In this section, we describe how to divide the program into e-blocks. The only condition for several consecutive lines of code to form an e-block is that there is a single entry point. Whenever control is transferred from one e-block to another, the control must be transferred to the entry point of the second e-

---

![Figure 5.1. Log Intervals](image-url)
block, where the prelog is made. The postlog is made at the exit point where the control is transferred out of an e-block. One natural candidate for constructing an e-block is the subroutine, since the entry and the exit points are well defined. (Actually, an e-block could be any node of the control dependence graph in PDG [14], since the entry and exit points of each node in PDG are well defined.)

The size of e-blocks is crucial to the performance of the system during the execution and debugging phases. In general, if we make the size of the e-blocks large in favor of the execution phase, the debugging phase performance will suffer. On the other hand, if we make the size of the e-blocks small in favor of the debugging phase, execution phase performance will suffer. While the number of logging points should be small enough so as not to introduce unacceptable performance degradation during the execution phase, it should also be large enough so as not to introduce unacceptable time delay in generating fine traces during the debugging phase. Consider, for example, the case in which the size of a subroutine is very large. Though the size of a subroutine has no direct relationship to the time needed to execute it, we can act conservatively to construct several e-blocks out of such a large subroutine.

Loop constructs, even though small in size, may require long execution time and thus introduce unacceptable time delay in generating fine traces. Currently, the PPD compiler constructs one e-block from each loop. However, the compiler constructs only one e-block from the outermost of multiply nested loops. Defining e-blocks for loops allows the debugging phase to proceed without excessive time spent in re-executing the loops. Still, if the user is interested in the execution details inside such loops, we can re-execute the e-blocks corresponding to the loops.

Three elements can affect the program behavior of an e-block: the initial state as recorded by the pre-log, the code of the e-block, and input statements in the e-block. We need to accommodate input statements in an e-block to make the behavior of the e-block during debugging the same as that during execution. We can make each input statement an e-block, whose DEFINED set consists of the variables affected by the input statement.

5.3. Log Optimization

Small and frequently called subroutines can be a problem. If we make an e-block out of each small subroutine, the amount of logging done during the execution phase may be large enough to introduce unac-
ceptable performance degradation. To avoid this problem, it may be better not to make e-blocks out of
subroutines that do not contain subroutine calls (i.e., subroutines that correspond to leaf nodes in the call
graph). If an e-block is not formed from such a subroutine, then the subroutine itself does not perform any
logging. Instead, the e-blocks that call this subroutine (its parent e-blocks in the call graph) perform its
logging. However, a subroutine that either contains a loop or contains accesses to a static variable (in the C
language) is not eligible for such optimization. This process can be applied recursively to the parent e-
blocks, and continue any number of levels up the call graph (as specified by the user) until an e-block is
reached that is ineligible for optimization.

5.4. Locating Log Intervals for Incremental Tracing

When the debugging phase starts, we generate fine debugging time traces for the last log interval —
the log interval that contained the last statement executed. (The last log interval usually lacks the postlog
when the execution halted due to an error or user intervention.) This allows the initial dynamic graph to be
constructed. From then on, there are three cases when we need to generate fine traces for a new log inter-
val: (1) when the user wants to know the details of the dependences of a parameter passed from a calling
subroutine, (2) when the user wants to know the details of a hidden dependence edge — a dependence edge
that either terminates into or comes out of a sub-graph node, or (3) when the user wants to know the details
of a dangling dependence (a dependence for a variable that is read in an e-block before it is written).

When the user wants to know the detailed dependence of a parameter, we can easily locate the log
interval needed to generate fine traces; the log intervals are nested as in Figure 5.2, and the caller’s log
interval is the one enclosing the current log interval. When the user wants to know the detailed dependence
of a function return value, we can also easily locate the needed log interval; the callee’s log interval is one
of those log intervals nested in the current log interval, and log intervals at the same nesting level are
generated in the execution order of the called subroutines.

When the user wants to know the details of a hidden or dangling dependence, we need to identify the
log interval needed to generate fine traces to show the details. To facilitate identifying such log intervals,
we obtain the DEFINED set of each e-block during compile time and keep it as part of the program data-
base [28]. We also keep in the program database, for each variable that might be accessed by more than
one e-block, the list of e-blocks that contain the variable in their DEFINED sets. We call the list the e-block table. The e-block table in Figure 5.2 shows the list of e-blocks for three variables: "g1", "g2", and "g3".

Figure 5.2 also shows an example log file. Log entries generated by the same e-block form a linked list; each postlog has two pointers: one pointing to its corresponding prelog, and the other pointing to the most recent postlog made by the same e-block. E-pointers is an array of pointers to the last log entry made by each e-block and is updated during program execution.

To locate the most recent log interval that contains a modification to a variable, we first retrieve the list of e-blocks that contain the variable in their DEFINED sets. The list of e-blocks is stored in the e-block
table. We then locate either the most recent postlog produced by any of these e-blocks in the case of hidden dependence, or the most recent prelog in the case of dangling dependence. We finally generate the fine traces by using the emulation package for that e-block and the log entries for that log interval. This process may need to be repeated if the e-block did not actually modify the variable or if the last modification of the variable in the e-block occurred before a nested e-block that also potentially modifies the variable [9].

When we construct more than one e-block out of a subroutine because of debugging time efficiency considerations, we sometimes need to locate an e-block that might write a local variable. Unlike global variables, a variable local to a subroutine has an instance in each execution instance of the subroutine and we should not use log entries generated by different execution instances of the subroutine for the detailed dependence of a local variable.

5.5. Arrays and the Log

For an e-block with array accesses, it is not possible to compute USED and DEFINED sets that contain only those array elements that are actually accessed in the e-block. One approach is to generate a log entry for the entire array even if only a few array elements are accessed. A second approach is to simply trace every array access. However, both approaches can potentially generate large amount of traces during execution.

Our solution to this problem is as follows. We distinguish two types of array accesses: systematic accesses and random accesses. We say there is a systematic access to an array if the array is accessed in a loop and the array index has a possibly transitive data dependence on the loop control variable. With a systematic access, we regard the entire array as accessed and generate a log entry (as usual) for the entire array. We regard all the other types of accesses to arrays as random accesses and generate a special log entry for the array index and the accessed value (read or updated value) of the array element at the time the access is made.

6. PARALLEL PROGRAMS AND FLOWBACK ANALYSIS

The discussion so far has described mechanisms to efficiently implement flowback analysis for sequential programs. In this section, we discuss the mechanisms for extending flowback analysis to parallel programs. For parallel programs, data dependences may exist across process boundaries. Locating
such data dependences involves constructing a version of the dynamic graph that contains the events belonging to all processes, and then ordering the events in this graph. With additional logging of shared variables, the incremental tracing scheme described in Section 5 can then be used to establish dependences between processes. In addition, potential data races in the program execution can be detected.

6.1. Parallel Dynamic Graph and Ordering Concurrent Events

To apply flowback analysis to parallel programs, we construct a version of the dynamic graph, called the *parallel dynamic graph*, that contains the events belonging to all processes in the program execution. To this graph we add edges that allow us to determine the order in which these events executed. From this ordering, data dependences can be established across process boundaries, and data races can be detected. We now describe how the parallel dynamic graph is constructed and the necessary run-time information that must be recorded to do so. We then show how this graph orders the events belonging to different processes, and how this ordering allows intra-process data dependences, and data races, to be detected.

![Figure 6.1. An Example Parallel Dynamic Graph](image)

---

*TR 786*  
*REVISED*  
*February 2, 1990*
6.1.1. Parallel Dynamic Graph

The parallel dynamic program dependence graph (or parallel dynamic graph) is an abstraction of the dynamic graph that shows the interactions between processes while hiding the detailed dependences of local events. This graph contains only one node type, the synchronization node, and two edge types, the synchronization edge and internal edge (Figure 6.1 shows an example of a parallel dynamic graph). A synchronization node is constructed for each synchronization operation in the program execution. A synchronization edge from one node to another indicates that the first node executed before the second node. An internal edge abstracts out all events (belonging to the same process) that executed between the synchronization operations connected by the edge. For example, in Figure 6.1, all the events of process \( p_1 \) that executed before event \( n_{1,1} \), also executed before all those events of process \( p_2 \) that executed after event \( n_{2,1} \). The synchronization edge between \( n_{1,1} \) and \( n_{2,1} \) can be viewed as a generalized flow edge that spans the two processes.

We now describe how to construct synchronization edges for programs that use semaphores. Other synchronization primitives (such as messages, rendezvous, etc.) can also be handled [9]. In general, we construct a synchronization edge between two nodes if we can identify the temporal ordering between them. We say that the source node of an edge is the node connected to the tail of the edge, and the sink node of an edge is the node connected to the head of the edge.

Semaphore operations, such as P and V, are used in controlling accesses to shared resources by either acquiring resources (through a P operation) or releasing resources (through a V operation). We construct a synchronization edge from the node representing each V operation to the node representing some P operation on the same semaphore. Each V operation, which releases resources, is paired with the P operation that acquires those released resources.

There are two cases to be considered. The first case is where the second process tried to acquire the resources before the first process released them; the second process thus blocked on the P operation until the V operation of the first process. The second case is where the first process released the resources before the second process tried to acquire them; the second process did not block on the P operation in this case. In both cases, we define a source node for the V operation and a sink node for the corresponding P operation. The operations on a semaphore variable are serialized by the system that actually implements
semaphore operations, and identifying a pair of related semaphore operations is done by matching the \( n^{th} \) V operation to the \((n+i)^{th}\) P operation on the same semaphore variable, where \( i \geq 0 \) is the initial value of the semaphore variable.

Additional logging is necessary to record the information required to determine this semaphore pairing. Each semaphore operation generates a log entry (for the process it belongs to) containing a counter indicating how many operations on the given semaphore have previously been issued. The semaphore operations can easily be paired and the synchronization edges constructed from these log entries.

6.1.2. Ordering Events

In the parallel dynamic graph, each internal edge represents the set of events bounded by the surrounding synchronization operations. The order in which two events executed can be determined if there is a path between the two internal edges that represent those events. If no such path exists, then the two events either executed concurrently or may have potentially executed concurrently. We partially order the nodes and edges of the parallel dynamic graph by defining the \textit{happened-before} relation [25], \( \rightarrow \), as follows:

1) For any two nodes \( n_1 \) and \( n_2 \) of the parallel dynamic graph, \( n_1 \rightarrow n_2 \) is true if \( n_2 \) is reachable from \( n_1 \) by following any sequence of internal and synchronization edges.

2) For two edges \( e_1 \) and \( e_2 \), \( e_1 \rightarrow e_2 \) is true if \( n_1 \rightarrow n_2 \) is true where \( n_1 \) is the sink node of the edge \( e_1 \), and \( n_2 \) is the source node of the edge \( e_2 \).

There are several approaches to ordering events in a parallel program execution [9, 13, 15, 16, 25, 30]. Although the ordering between two events can be determined by searching for a path in the graph, a more efficient representation of the happened-before can be constructed that allows the order between any two events to be determined in constant time. Such a representation is constructed by scanning the graph and computing, for each node, two vectors that show the earliest (or latest) nodes in all processes that happened before (or after) that node [9].
6.1.3. Data Races

One purpose of adding (explicit) synchronization to a parallel program is to ensure that some sections of code execute as if they were atomic. In shared-memory parallel programs, failure to ensure this atomicity is one source of nondeterminism, and is usually a symptom of a bug. A section of code executes as if it were atomic if the shared variables it reads and modifies are not modified by any other concurrently executing section of code. A data race exists between two concurrently executing sections of code if they both access a common shared variable, and at least one of them modifies that variable. When no data races exist, atomicity is guaranteed, and the incremental tracing scheme described in Section 5 can be extended to re-execute parts of the program. In addition, all events that modify a shared variable can be ordered (by the happened-before relation), so data dependences can be located across process boundaries. Flowback analysis can therefore be applied to program executions that are data-race free. When data races do exist, we can detect them, and direct the user to a set of potential data races.

Definition 6.1

Two edges \( e_1 \) and \( e_2 \) are simultaneous edges if \( \neg (e_1 \rightarrow e_2) \land \neg (e_2 \rightarrow e_1) \).

Definition 6.2

\( READ\_SET(e_i) \) is the set of the shared variables read-accessed in edge \( e_i \). \( WRITE\_SET(e_i) \) is the set of the shared-variables write-accessed in edge \( e_i \).

Definition 6.3

We say two simultaneous edges \( e_1 \) and \( e_2 \) are data-race free if all the following conditions are true:

a) \( WRITE\_SET(e_1) \cap WRITE\_SET(e_2) = \emptyset \).

b) \( WRITE\_SET(e_1) \cap READ\_SET(e_2) = \emptyset \).

c) \( READ\_SET(e_1) \cap WRITE\_SET(e_2) = \emptyset \).

Definition 6.4

An execution instance of a program is said to be data-race free if all pairs of simultaneous edges in the execution instance are data-race free.

If two edges are simultaneous, it does not necessarily mean that all the events comprising the edges executed concurrently. Rather, it means that not enough run-time information was recorded to determine their actual execution order. It is for this reason that we can only detect when a program execution is data-race
free. When an execution is not data-race free, a set of potential data races (between edges that are not data-race free) can be detected. However, this approach always detects data races when they exist and only reports a data race when at least one occurs [30].

To precisely determine when the program execution is data-race free, the shared variables that are read-accessed and write-accessed by the events represented by each internal edge must be recorded. For this purpose we generate bit-vectors of the basic blocks potentially executed by these events [4]. These bit-vectors (generated and traced during run time) and the sets of shared variables accessed in each basic block (computed during compile time) allow the set of shared variables actually read-accessed and write-accessed to be determined.

This data race detection scheme is similar to other methods [4, 12, 30, 32], with the exception of pairing the P and V operations.

6.1.4. Data Dependences for Parallel Programs

We now show how to extend data dependence edges across process boundaries for a data-race-free execution. Given a read event for some shared variable, its data dependence is located by finding the most recent write event that happened before that read. For each process, the latest edge that happened before the edge containing the read event is located. These edges give a boundary beyond which all events either executed concurrently with or after the read event. Next, the log for each process is scanned backwards from this boundary to find an edge whose WRITE_SET contains the shared variable in question. Finally, the ordering of all such write events is examined to determine which one executed last. A data dependence can then be drawn from this event to the read event. The incremental tracing scheme outlined below (in Section 6.2) can then be employed to generate the fine traces needed to construct the dynamic graph for the log interval that contains the dependence.

Figure 6.3 shows an example of a parallel graph in which a shared variable "SV" is read by process \( p_3 \) and modified by processes \( p_1 \) and \( p_2 \). To establish the data dependence edge for "SV", the most recent modification of "SV" that occurred before the read must be located. If events belonging to edges \( e_{2,1} \) (the edge emanating from node \( n_{2,1} \)) and \( e_{1,0} \) (the topmost edge of process \( p_1 \)) are the only modifications of "SV", then a data dependence is established between the event in \( e_{2,1} \) that modified
"SV" and the event in $e_{3,1}$ that read "SV". If, for example, there exists another event that modified "SV" in any of the edges $e_{1,1}, e_{1,2}, e_{2,2}, e_{2,3},$ or $e_{2,4}$ (i.e., edges simultaneous to $e_{3,1}$), then we cannot tell which event actually modified "SV" last, and a data race is reported to the user.

6.2. Incremental Tracing For Parallel Programs

Our implementation of incremental tracing described in Section 5 relied on the reproducibility of the debugged program. We now discuss applying incremental tracing to shared-memory parallel programs that lack reproducibility. Our solution uses a graph called the simplified static graph, which is a subset of the static graph that abstracts out everything except the synchronization operations between processes. From this graph, we determine what additional logging is required to support incremental tracing.

6.2.1. Simplified Static Graph

To motivate the construction of the simplified static graph, consider the example shown in Figure 6.4, which contains a subroutine that accesses a global variable named "SV". The subroutine also
```c
int SubB ()
{
    int a, b, c, p, q;
    if (p==...)
        if (q==...)
            ...
        else /* q */
            ...
    SubC();
    /* q */
    else /* p */
        SV=a+b+SV;
    SubA();
    ...
} /* p */
} /* SubB */

□ : branching node
○ : non-branching node

† This node corresponds to the subroutine call of SubA.
• This node corresponds to the subroutine call of SubC.

Figure 6.4. A Subroutine and Its Simplified Static Graph

constitutes an e-block. The statement indicated by the arrow is the first statement that accesses the variable "SV" in this subroutine. In the case of a sequential program, we construct a prelog that saves the value of "SV" at the beginning of the subroutine. The value of "SV" will not be changed until it is first accessed in the statement indicated by the arrow. Hence, one prelog and one postlog is sufficient to obtain reproducible behavior when re-executing parts of sequential programs during debugging.

However, now consider the case of a parallel program. If "SV" is a shared variable, we cannot guarantee that the value of "SV" saved in the prelog at the beginning of the subroutine will be the same as when "SV" is first read; other processes may have changed the value of "SV" between these two moments. Re-execution of this e-block may therefore perform a different computation that was originally performed during execution. In general, more run-time information must be recorded to ensure reproducibility of parallel programs. Such additional information is used to restore the program state for read-
accessed shared variables. The simplified static graph allows us to determine which shared variables must be recorded and where in the program they should be logged. In our examples, we only consider semaphore operations; however, this approach can be generalized to other synchronization primitives.

The simplified static graph is a subset of the static graph that contains only flow edges and nodes that represent either possible control transfers (such as if or case statements) or semaphore operations (Figure 6.4 also shows the simplified static graph for subroutine SubB). Any sub-graph node representing a subroutine that may perform a semaphore operation during its execution (or during the execution of any subroutine that may be transitively called by it) is treated as a semaphore operation. The simplified static graph therefore contains only branching nodes, which represent possible control transfers, and non-branching nodes, which represent possible semaphore operations.

6.2.2. Synchronization Units and Additional Logging

To generate the additional logging for shared variables, the simplified static graph is partitioned into synchronization units, which identify which shared variable to record and where in the program they should be logged.

Definition 6.5

A synchronization unit consists of all the edges that are reachable from a given non-branching node in the simplified static graph without passing through another non-branching node.

The sets \( \{e_1, e_2, e_3, e_5, e_6, e_8, e_9\} \), \( \{e_4, e_9\} \), and \( \{e_7, e_8, e_9\} \) in Figure 6.4 each constitute a synchronization unit.

The object code generates an additional prelog at the beginning of each synchronization unit for those shared variables that are potentially read-accessed inside the synchronization unit. There is no corresponding postlog generated for the write-accessed shared variables at the end of a synchronization unit, as the regular logs generated at the beginning and end of the e-block contain the values of both shared and non-shared variables. The additional prelog of the read-accessed shared variables is used to ensure repeatable re-execution of the events in the synchronization unit. As long as there were no data races during execution, the additional prelog will suffice for ensuring repeatable execution behavior during debugging.
7. PERFORMANCE MEASUREMENTS

This section presents measurements of the overhead caused by PPD on execution time of application programs. We compare the execution time of the object code generated by the PPD compiler with that generated by the Sequent Symmetry C Compiler. We also present measurements of execution-time trace size. There is a trade-off between the amount of trace generated during execution time and the amount generated during debug time. The trade-off is based on selecting the size and location of e-blocks. Our current heuristics for making this selection are quite simple, so the performance numbers give only an initial indication of the cost of using PPD.

We present measurement results of five test programs: SORT, MATRIX, SH_PATH_1, SH_PATH_2, and CLASS. SORT sorts a vector of 100 integers using an Insertion Sort algorithm, whose time complexity is $O(n^2)$. MATRIX multiplies two square matrices of integers into a third matrix. The size of each matrix, for our tests, is 100 by 100. MATRIX uses a subroutine in multiplying two scalar elements of the two matrices. The subroutine does not contain a loop or accesses to a static variable, making that subroutine a target of log optimization (see Section 5.3). SH_PATH_1 computes the shortest paths from a city to 99 other cities using an algorithm described by Horowitz and Sahni [17]. SH_PATH_2 is the same as SH_PATH_1 except that it computes the shortest paths from all of the 100 cities to all the other cities. CLASS is a program that emulates course registration for students, such as registering for courses, and dropping from courses. CLASS also can run as an interactive program.

7.1. Execution Time

The goal of the PPD design is to minimize execution-time overhead without unduly burdening the other phases of program execution. Figure 7.1 shows the execution-time overhead of the tested programs. Execution-time overhead ranges 0–330% for object code that is not log-optimized, and 0–75% for object code that is log-optimized. MATRIX has the largest performance improvement from log optimization. The execution-time overhead of MATRIX is reduced from 330.7% to 7.9%. MATRIX has a subroutine that is called one million (100 by 100 by 100) times by another subroutine. Without log optimization, each call to this subroutine generates a prelog-postlog pair, resulting in a large execution-time overhead (due to the one million prelog-postlog pairs). However, this subroutine does not have a loop or accesses to static
\begin{table}
\centering

\hline
 & Sequent Compiler & PPD compiler w/o log optimization (overhead in \%) & PPD compiler w/ log optimization (overhead in \%) \\
\hline
SORT & CPU & 5.5 & 5.7 (3.6\%) & 5.7 (3.6\%) \\
& Elapsed & 5.6 & 6.1 (8.9\%) & 6.1 (8.9\%) \\
\hline
MATRIX & CPU & 12.7 & 52.5 (313.4\%) & 13.4 (5.5\%) \\
& Elapsed & 12.7 & 54.7 (330.7\%) & 13.7 (7.9\%) \\
\hline
SH_PATH_1 & CPU & 1.1 & 1.8 (63.6\%) & 1.8 (63.6\%) \\
& Elapsed & 1.3 & 2.2 (69.2\%) & 2.2 (69.2\%) \\
\hline
SH_PATH_2 & CPU & 107.0 & 105.5 (-2.4\%) & 105.5 (-2.4\%) \\
& Elapsed & 107.0 & 107.3 (2.8\%) & 107.3 (2.8\%) \\
\hline
CLASS & CPU & 0.3 & 0.4 (33.3\%) & 0.4 (33.3\%) \\
& Elapsed & 0.4 & 0.7 (75.0\%) & 0.7 (75.0\%) \\
\hline
\end{tabular}
\caption{Test Program Execution Time Measurements (time in seconds)}
\end{table}

variables; with log optimization, this subroutine becomes a non-e-block subroutine and the caller becomes the parent e-block. The non-e-block subroutine does not generate log entries, yielding a much smaller execution time. Accordingly, log optimization also causes MATRIX to have a large reduction in the size of execution-time traces.

Log optimization might actually produce a higher execution-time overhead if the non-e-block subroutine is never invoked due to conditional statements in the program; parent e-blocks of these non-e-block subroutines may generate additional log information for the non-e-block subroutines that are never invoked. However, we expect that such cases of losing by log optimization should be rare.

We also see that copying the contents of an entire array (for a log entry) at the beginning or at the end of a loop is inexpensive in terms of execution time overhead if most of the array elements are actually accessed in the loop. Such is the case with program SH_PATH_2. However, if only a fraction of the array elements are accessed in a loop, dumping out an entire array can be expensive, as seen in test program
SH_PATH_1. One possible way to reduce this overhead is to generate a smaller log entry containing only the particular row (or other part) of the matrix that is actually accessed by employing techniques for succinctly summarizing data accesses in arrays [5].

Array logging can also cause some interesting performance anomalies. Notice that test program SH_PATH_2 shows a slight improvement in CPU time (the sum of user and system time) with the code generated by the PPD compiler. The PPD compiler generates logging code immediately before the loop that accesses a large array; the logging code accesses the entire array. This extra access seems to affect the paging behavior (possibly at the architecture level) of the program, resulting in less execution time. We are currently investigating this anomaly.

Program CLASS can also run as an interactive program. While there is a 33% increase in CPU time and a 75% increase in elapsed time when CLASS ran using an input file, there was no noticeable difference in the response times when CLASS ran interactively.

Figure 7.2. Execution-Time Trace Size Measurements
(sizes in bytes)
7.2. Execution-Time Trace Size

Figure 7.2 shows the sizes of execution-time traces (log) generated by the test programs. As described before, program MATRIX has a substantial decrease in trace size from log optimization. Program CLASS has a slight increase in trace size from log optimization because of the reason described previously.

7.3. Trade-Off between Run Time and Debug Time

As described in Section 3, there is a trade-off between efficiency during execution and response time during debugging. If we construct an e-block in favor of the execution phase, debugging phase performance will suffer. On the other hand, if we construct an e-block in favor of debugging phase, execution phase performance will suffer.

Figure 7.3 shows the re-execution times and debug-time trace sizes of various e-blocks of the tested programs. The e-block from SORT consists of a singly-nested loop that sorts the list of numbers once. The e-block of MATRIX is made of a triply nested loop. By constructing a single e-block out of the triply nested loop of MATRIX, we were able to reduce the execution phase overhead, but with a large debug-time overhead: 166 seconds in re-execution time and 61 Mbytes of debug-time trace. For a comparison, the execution time of MATRIX itself is about 13 seconds, and execution-time trace size is 0.12 Mbytes, with log optimization. The e-block of SH_PATH_1 in Figure 7.3 is constructed out of a singly nested loop that computes the shortest paths from a city to 99 other cities, while the e-block of SH_PATH_2 is constructed out of a doubly nested loop that computes the shortest paths from 100 cities to all the other cities. The e-block of SH_PATH_1 took about 5 seconds to execute with 1.3 Mbytes of trace, while the e-block of SH_PATH_2 terminated because the file system was full.† At that time the e-block of SH_PATH_2 lasted more than 5 minutes with more than 100 Mbytes of trace. These two results suggest that it might sometimes be better to construct more than one e-block out of a nested loop. One alternative might be to generate more than one prelog-postlog pair for an e-block with long execution time (such as an e-block made

† The re-execution failure of this e-block is an artifact of our current implementation. The emulation package code writes out the entire fine trace to a file, and then the file is subsequently read by the controller to build the dynamic graph. Since the trace file is read in a single sequential pass, it can be consumed directly by the controller. The data can be passed, via a pipe, to the controller, removing any limitations on disk space. This change would most likely also result in lower re-execution times.

out of a nested loop). In this case, the decision whether to generate another prelog-postlog pair during the execution of an e-block could be made dynamically at execution time.

7.4. Summary of Measurements

In this section, we have provided performance measurements of the various parts of PPD. The measurements show increases in the execution time vary significantly (0%–86%) among the test programs. However, larger increases in the execution time come from test programs that access only part of arrays in loops. One possible way to reduce this overhead is to employ techniques for succinctly summarizing data accesses in arrays [5]. With a more sophisticated dependence analysis for such complex objects, we expect a reduction in the execution-time overhead.

Execution-time trace sizes are generally small (less than 1 Mbyte in all cases). However, the measurements show that we need more experiments and research to better balance between the trace size during execution and the response time during debugging.

The test programs used in the performance measurements of PPD are in general small in size. However, we think the results obtained with these program will scale up proportionally well with programs of
large size. In general, the performance measurements of PPD described in this section have demonstrated the feasibility of the ideas and directions proposed in our approach for debugging parallel programs.

8. CONCLUSION

Flowback analysis debugging has several advantages. First, we show the dynamic data dependences, so the programmer can directly see casual relationships. Second, we do not require repeated execution, avoiding many of the problems encountered in trying to find non-deterministic bugs. Third, we help detect one of the more difficult synchronization errors, data races, in a program execution.

The graphs and algorithms presented in this paper provide the foundation for the construction of the system that will do efficient flowback analysis for parallel programs. Several ideas make efficient flowback analysis possible. The use of semantic analysis allows us to identify at compile time only those variables that are necessary to trace at execution time. The incremental generation of the detailed traces at debugging time further amortizes the cost of tracing over the interactive debugging session. The fragmented static graph structure used in PPD is easily built and is tailored to be the building block of the dynamic graph. With the inclusion of synchronization dependences, these graph structures generalize nicely to parallel programs.

There are several issues that must still be addressed in the PPD design. The most immediate issue is the handling of pointers and dynamic data structures. The methods described in Section 3 form a starting point, and we are currently working on this problem. The user interface design is another area that must be investigated. A graphical representation of program dependences can offer quick access to complex structures. But as the body of displayed information increases, these displays can quickly overwhelm the viewer. A careful trade-off between graphical and textual information using multiple views and supporting information will be necessary to provide an intuitive interface.

We believe that PPD can be a platform for more than interactive debugging. Currently, the decision about which variable’s dependences to examine is made by the programmer. Flowback analysis could be integrated with a more automated decision making process. This might be a verification system based on formal specifications or an expert system based on debugging knowledge.
Many of the design decisions and heuristics in PPD must be evaluated in practice. A working prototype is under construction to test our decisions on real programs. These tests will allow us to evaluate overall effectiveness and to tune the algorithms for such things as selecting e-block sizes and handling large arrays. An initial implementation of PPD (including all of the facilities described in this paper) is running, using the C programming language, on a Sequent Symmetry shared-memory multiprocessor.
