# **Context-Free-Language Ordered Binary Decision Diagrams**

MEGHANA APARNA SISTLA, The University of Texas at Austin, USA

SWARAT CHAUDHURI, The University of Texas at Austin, USA

THOMAS REPS, University of Wisconsin-Madison, USA

This paper presents a new compressed representation of Boolean functions, called CFLOBDDs (for Context-Free-Language Ordered Binary Decision Diagrams). They are essentially a plug-compatible alternative to BDDs (Binary Decision Diagrams), and hence useful for representing certain classes of functions, matrices, 10 graphs, relations, etc. in a highly compressed fashion. CFLOBDDs share many of the good properties of BDDs, 11 but-in the best case-the CFLOBDD for a Boolean function can be exponentially smaller than any BDD for that 12 function. Compared with the size of the decision tree for a function, a CFLOBDD-again, in the best case-can 13 give a double-exponential reduction in size. They have the potential to permit applications to (i) execute much 14 faster, and (ii) handle much larger problem instances than has been possible heretofore. 15

We applied CFLOBDDs in quantum-circuit simulation, and found that for several standard problems the improvement in scalability, compared to BDDs, is quite dramatic. With a 15-minute timeout, the number of qubits that CFLOBDDs can handle are 65,536 for GHZ, 524,288 for BV; 4,194,304 for DJ; and 4,096 for Grover's Algorithm, besting BDDs by factors of 128×, 1,024×, 8,192×, and 128×, respectively.

Additional Key Words and Phrases: Decision diagram, matched paths, best-case double-exponential compression, quantum simulation

#### 1 **INTRODUCTION**

Many areas of computer science-such as hardware and software verification, logic synthesis, and 24 equivalence checking of combinatorial circuits-require a space-efficient representation of data, as 25 well as space- and time-efficient operations on data stored in such a representation. Many of the 26 tasks in the aforementioned areas involve operations on either (i) Boolean functions, or (ii) non-27 Boolean-valued functions over Boolean arguments. In some cases, a level of encoding is involved: the 28 data of interest could be decision trees, graphs, relations, matrices, circuits, signals, etc., which are 29 encoded as functions of type (i) or (ii). Binary Decision Diagrams (BDDs) [11] are one data structure 30 that is widely used for such purposes. A Boolean function in  $B_n = \{0, 1\}^n \rightarrow \{0, 1\}$  is represented 31 in a compressed form as an ROBDD (Reduced Ordered BDD) data structure. All manipulations of 32 these Boolean functions are carried out using algorithms that operate on ROBDDs. ROBDDs are 33 BDDs in which the same variable ordering is imposed on the Boolean variables ("Ordered"), and 34 so-called don't-care nodes are removed ("Reduced"). ROBDDs with non-binary-valued terminals 35 are called Multi-Terminal BDDs (MTBDDs) [13, 15] or Algebraic Decision Diagrams (ADDs) [3]. 36 We will refer to ROBDDs/MTBDDs/ADDs generically as BDDs from hereon. 37

- 49

In the programming-languages community, BDDs are widely used for program analysis and have been used in Datalog interpreters.

- The SLAM system (later called Static Driver Verifier) was a Microsoft tool for checking temporal properties of device drivers (e.g., that drivers correctly follow API-usage rules) [5]. BDDs were used in SLAM to represent the abstract transformers of Boolean programs that were abstractions of a driver's source code. BDDs allowed the SLAM developers to increase the capabilities of the IFDS framework for interprocedural dataflow analysis [54] to handle relations over valuations over a Boolean program's Boolean variables [6].
  - The Datalog solver bddbddb, which uses BDDs as the backing representation of relations, was developed by Whaley and Lam to support a variety of program analyses [65, 66].
  - Lhoták used BDDs in interprocedural program analyses to represent and manipulate collections of large sets, allowing him to use larger programs than previous studies of the factors that affect analysis precision [37].

In some applications of BDDs, the initial and final BDD structures are of a reasonable size, but there is an "intermediate swell" during the computation. Such a blow-up can cause operations to take a long time, or cause an application to run out of memory. The size-explosion issue generally limits the use of BDDs to problems involving at most a few hundred Boolean variables.

In this paper, we introduce a new data structure, called *Context-Free-Language Ordered Binary* 68 Decision Diagrams (CFLOBDDs), which are essentially a plug-compatible replacement for BDDs. 69 CFLOBDDs share many of the good properties of BDDs, but-in the best case-the CFLOBDD 70 for a Boolean function can be exponentially smaller than any ROBDD for that function. Compared 71 with the size of the decision tree for a function, a CFLOBDD-again, in the best case-can give 72 a double-exponential reduction in size. Obviously, not every Boolean function has such a highly 73 compressed representation, but for the ones that do, CFLOBDDs offer much better compression 74 than BDDs, and thus have the potential to permit applications to (ii) execute much faster, and (ii) 75 handle much larger problem instances than has been possible heretofore. 76

CFLOBDDs can represent functions, matrices, graphs, relations, etc. (using binary- or multi-77 valued terminals, as appropriate). Even for objects for which double-exponential compression is 78 not achieved, CFLOBDDs may provide better compression than BDDs. Like BDDs, CFLOBDDs are 79 canonical (§4), and operations are performed on them directly (§6): they are never unfolded to the 80 full decision tree. Moreover, an implementation can ensure that only a single representative is ever 81 constructed for a given function; consequently, the test of whether two CFLOBDDs represent equal 82 functions can be performed merely by comparing the values of two pointers. 83

CFLOBDDs are based on the following insight:

A BDD can be considered to be a special form of bounded-size, branching, but non-looping program. From that viewpoint, a CFLOBDD can be considered to be a bounded-size, branching, but non-looping program in which a certain form of procedure call is permitted.

The advantages of this idea are two-fold. First, whereas a BDD of size n can have at most  $2^n$  paths, 89 the "procedure-call" mechanism in CFLOBDDs allows a CFLOBDD of size *n* to have  $2^{2^n}$  paths 90 (§3.5.1). This difference is what lies behind the potential compression advantage of CFLOBDDs. Second, even when best-case compression is not possible, such "procedure calls" allow there to 92 be additional sharing of structure beyond what is possible in BDDs: a BDD can share sub-DAGs, 93 whereas a procedure call in a CFLOBDD shares the "middle of a DAG." (See Figs. 3 and 6.) 94

We evaluated CFLOBDDs and BDDs on synthetic benchmarks and for quantum simulation. We compared the performance in terms of size and execution time: on problem sizes for which both approaches ran successfully, CFLOBDDs were generally smaller and had lower execution

times, particularly at the upper end of the capabilities of BDDs. Moreover, the improvement that
 CFLOBDDs bring in scalability is quite dramatic, both for the synthetic benchmarks (§10.2.1) and
 for quantum simulation (§10.2.2).

• We introduce a new data structure, called CFLOBDDs, for representing functions, matrices, graphs, relations, and other discrete structures in a highly compressed fashion (§3). In the best case, a CFLOBDD obtains double-exponential compression in space: i.e., the CFLOBDD for a Boolean function f is double-exponentially smaller than the decision tree for f. • We present *algorithms* for creating CFLOBDDs and performing operations on them (§6). Most operations have low cost: unary operations are either constant-time or linear in the size of the argument CFLOBDD; the cost of most binary operations is bounded by the product of the sizes of the two argument CFLOBDDs. Moreover, for many of the functions of  $2^k$  variables 

for which the CFLOBDD representation is double-exponentially smaller than a decision tree of size  $2^{2^k}$ , the CFLOBDD can be constructed in time O(k) and space O(k).

• We show an *exponential gap* between CFLOBDDs and BDDs (§8).

Our work makes the following contributions:

- We describe how CFLOBDDs can be used to simulate quantum circuits (§9.4).
- We measured the performance of CFLOBDDs and BDDs on synthetic and quantumsimulation benchmarks (§10). For several problems, the improvement in scalability enabled by CFLOBDDs is quite dramatic. In particular, in the quantum-simulation benchmarks, the number of qubits that could be handled using CFLOBDDs was larger, compared to BDDs, by a factor of 128× for GHZ; 1,024× for BV; 8,192× for DJ; and 128× for Grover's algorithm.

Organization. §2 reviews decision trees and BDDs. §3 introduces the basic principles underlying CFLOBDDs. §4 introduces some additional structural invariants that allow us to establish that each Boolean function has a unique, canonical representation as a CFLOBDD. §5 discusses how some standard techniques—hash-consing [23] and function-caching (or *memo functions* [45]) —apply to CFLOBDDs. §6 presents algorithms for a variety of CFLOBDD operations. §7 discusses how to represent matrices and vectors using CFLOBDDs, and how to perform some important operations on them. §8 demonstrates an exponential gap between CFLOBDDs and BDDs: the CFLOBDD for a function f can be exponentially smaller than any BDD for f. §9 discusses the application of CFLOBDDs to simulating quantum circuits. §10 poses two experimental questions and presents the results of experiments on synthetic and quantum-simulation benchmarks. §11 discusses related work. §12 concludes.

In consultation with the EIC, we have limited the presentation to about sixty pages. Additional material is available in reference [59]; citations of the form "[59, §X.Y]" indicate where omitted details can be found. The three most relevant appendices (§A–§C) are part of this paper.

#### 2 PRELIMINARIES: A FAMILY OF EXAMPLES, BOOLEAN FUNCTIONS, DECISION TREES, AND BDDS

This section presents the set of *Hadamard matrices*  $\mathcal{H}$ , which recur in §3 and §8–§10. It also reviews Boolean functions, decision trees, and BDDs, and shows how decision trees and BDDs can encode the members of  $\mathcal{H}$ .

*Hadamard Matrices.* The family of Hadamard matrices,  $\mathcal{H} = \{H_{2^i} \mid i \geq 1\}$ , can be defined recursively: for  $i \geq 1$ ,  $H_{2^{i+1}} = H_{2^i} \otimes H_{2^i}$ , with  $H_2$  from Fig. 1 as the base case. where  $\otimes$  denotes

Meghana Aparna Sistla, Swarat Chaudhuri, and Thomas Reps

Fig. 1.  $H_2$  and  $H_4$ , the first two members of the family of Hadamard matrices  $\mathcal{H} = \{H_{2i} \mid i \geq 1\}$ .

Kronecker product.<sup>1</sup> Fig. 1 shows  $H_2$  and  $H_4$ , the first two matrices in  $\mathcal{H}$ . The Kronecker product of two matrices is defined as

$$A \otimes B = \begin{bmatrix} a_{1,1} & \cdots & a_{1,m} \\ \vdots & \ddots & \vdots \\ a_{n,1} & \cdots & a_{n,m} \end{bmatrix} \otimes B = \begin{bmatrix} a_{1,1}B & \cdots & a_{1,m}B \\ \vdots & \ddots & \vdots \\ a_{n,1}B & \cdots & a_{n,m}B \end{bmatrix}$$

Equivalently,  $(A \otimes B)_{ii',jj'} = A_{i,j} \times B_{i',j'}$ . If A is  $n \times m$  and B is  $n' \times m'$ , then  $A \otimes B$  is  $nn' \times mm'$ . For  $i \ge 1$ ,  $H_{2^i}$  is a square matrix of size  $2^{2^{i-1}} \times 2^{2^{i-1}}$ . Thus, the number of rows/columns/entries in  $H_{2^{i+1}}$  is the square of the number of rows/columns/entries in  $H_{2^i}$ . For example,  $H_4$  is  $4 \times 4$ (16 entries);  $H_8$  is 16 × 16 (256 entries). An indexing scheme for  $H_{2^i}$  can be defined that uses  $2^{i-1} + 2^{i-1} = 2 * 2^{i-1} = 2^i$  Boolean variables. As shown in Fig. 1,  $H_2$  requires 2 variables— $x_0$  for the row index and  $y_0$  for the column index—whereas  $H_4$  requires 4 variables— $x_0$  and  $x_1$  for the row index, and  $y_0$  and  $y_1$  for the column index. In general,  $H_{2^i}$  can be treated as a function of type  $\{0,1\}^{2^{i-1}} \times \{0,1\}^{2^{i-1}} \rightarrow \{-1,1\}$ . Our convention is that  $x_0$  and  $y_0$  are the most-significant bits of the row and column indexes, respectively;  $x_1$  and  $y_1$  are the next-most-significant bits, respectively, etc.

Boolean Functions. A Boolean function over *n* variables is a function in  $\{F, T\}^n \to \{F, T\}$ . This paper is also concerned with pseudo-Boolean functions: a pseudo-Boolean function over n variables and value domain W is a function in  $\{F, T\}^n \to W$ . Because there is little chance of confusion, for brevity, we typically refer to such a function as a "Boolean function." We also use 0 and 1 as synonyms for *F* and *T*, respectively.

Hadamard matrix  $H_{2^i}$  can be considered to be a (pseudo-)Boolean function in  $\{0, 1\}^{2^i} \rightarrow \{-1, 1\}$ , with some convention about how the  $2^i$  input variables correspond to bits of the row-index and the column-index of the matrix.

Decision Trees. A decision tree is a tree representation of a Boolean function. For a Boolean function *B* in  $\{F, T\}^n \to W$ , the decision tree  $T_B$  for *B* is a complete binary tree with *n* plies and a value from W at each leaf.  $T_B$  comes with a specific ordering on the n Boolean inputs of B: each ply of  $T_B$  corresponds to some specific Boolean variable v among B's n Boolean input variables.  $T_B$ -and hence B-can be evaluated with respect to an input assignment  $[v_1 \mapsto b_1, \ldots, v_n \mapsto b_n]$ (where  $b_1, \ldots, b_n \in \{F, T\}$ ) by following a root-to-leaf path in  $T_B$ , returning the value that labels the leaf. (Note that  $v_1$  is not necessarily associated with the ply at the root. The order used by  $T_B$  is fixed, but can be any of the permutations of the sequence  $\langle v_1, \ldots, v_n \rangle$ .)

<sup>&</sup>lt;sup>1</sup> Others use a different indexing scheme:  $H_2$  is the same as with our scheme (as is  $H_4$ ), but the recursive definition is  $H_{2i+1} = H_2 \otimes H_{2i}$ , for  $i \ge 1$ . Thus, for  $i \ge 0$ ,  $H_{2i}$  is a  $2^i \times 2^i$  matrix (and thus has  $2^{2i}$  entries). In contrast, with our indexing scheme, the matrix we call  $H_{2i}$  is a  $2^{2^{i-1}} \times 2^{2^{i-1}}$  matrix, for  $i \ge 1$  (and thus has  $2^{2^i}$  entries). Put another way, what we call  $H_{2i}$  would conventionally be known as  $H_{22^{i-1}}$ . Not only do we avoid having to write a 

doubly superscripted subscript, we will see in §3.4 that the recursive rule " $H_{2^{l+1}}^{-1} = H_{2^l} \otimes H_{2^l}$ " fits particularly well with the internal structure of CFLOBDDs.

Fig. 2. Decision trees and BDDs for  $H_2$  and  $H_4$ , with plies in interleaved most-significant-bit order— $\langle x_0, y_0 \rangle$ and  $\langle x_0, y_0, x_1, y_1 \rangle$ , respectively. The bold paths show the assignments  $[x_0 \mapsto F, y_0 \mapsto T]$  (for  $H_2[0, 1]$ ) and  $[x_0 \mapsto F, y_0 \mapsto T, x_1 \mapsto F, y_1 \mapsto T]$  (for  $H_4[0, 3]$ ), respectively.

Figs. 2a and 2c show two decision trees, with the convention that will be used throughout the paper that at each interior node, the left branch is taken when the current Boolean variable in the assignment has the value *F* (or 0); the right branch is taken for the value *T* (or 1). Fig. 2a shows the decision tree for  $H_2$ , which has 2 plies, 3 interior nodes, and 4 leaf nodes, using the variable ordering  $\langle x_0, y_0 \rangle$ . In Fig. 2a, the path highlighted in bold is for the assignment [ $x_0 \mapsto F, y_0 \mapsto T$ ], which corresponds to  $H_2[0, 1]$  whose value is 1. Fig. 2c shows the decision tree for  $H_4$ , which has 4 plies and 15 interior nodes, using the interleaved-variable ordering  $\langle x_0, y_0, x_1, y_1 \rangle$ . The path in bold is for [ $x_0 \mapsto F, y_0 \mapsto T, x_1 \mapsto F, y_1 \mapsto T$ ], which corresponds to  $H_4[0, 3]$ , whose value is 1.

In Fig. 2c, the Kronecker product in the expression  $H_4 = H_2 \otimes H_2$  corresponds to *stacking decision trees.* In essence, the  $\langle x_0, y_0 \rangle$  plies correspond to the left occurrence of  $H_2$  in  $H_2 \otimes H_2$ ." At each "leaf" (the four interior nodes after the  $y_0$  ply), there is another copy of  $H_2$  in the  $\langle x_1, y_1 \rangle$  plies, with the terminal values labeled with the product of the left  $H_2$ 's value and the right  $H_2$ 's value. We can construct a decision tree for each member of  $\mathcal{H}$  by repeated stacking, doubling the number of plies each time in accordance with the definition  $H_{2^{i+1}} = H_{2^i} \otimes H_{2^i}$ .

Boolean functions and decision trees are related by the following fact:

OBSERVATION 2.1. Consider the sets of (i) Boolean functions in  $\{0, 1\}^n \to W$ , and (ii) n-ply decision trees with leaves labeled by values in W, using a variable ordering that is some fixed permutation of  $\langle v_1, \ldots, v_n \rangle$ . These sets can be put into one-to-one correspondence.  $\Box$ 

For each Boolean function  $B : \{0, 1\}^n \to W$ , create the *n*-ply decision tree  $T_B$  in which the value  $B(b_1, \ldots, b_n)$  is placed at the end of the path in  $T_B$  for the assignment  $[v_1 \mapsto b_1, \ldots, v_n \mapsto b_n]$ . Conversely, for each decision tree  $T_B$ , let *B* be the function in  $\{0, 1\}^n \to W$  for which  $B(b_1, \ldots, b_n)$ equals the value *w* at the end of the path in  $T_B$  for the assignment  $[v_1 \mapsto b_1, \ldots, v_n \mapsto b_n]$ . Finally, if two decision trees  $T_1$  and  $T_2$  represent the same Boolean function *B*, then the sequence of leaves in left-to-right order from each tree are equal, and thus  $T_1$  and  $T_2$  are the same tree (as a mathematical object). Thus, the *n*-ply decision trees that use a given variable ordering represent the Boolean functions in  $\{0, 1\}^n \to W$  uniquely.

*BDDs.* A BDD is a compressed representation of a decision tree. Fig. 2b shows the BDD for  $H_2$ , using the variable ordering  $\langle x_0, y_0 \rangle$ . Again, left branches are for F (or 0); right branches are for T (or 1). In the  $H_2$  matrix, rows 0 and 1 are different, and hence the BDD node for  $x_0$  is a *fork\_node*, which forks to two different substructures. In row 0 of the matrix, columns 0 and 1 are identical, and hence the  $y_0$  ply is skipped in the F branch of  $x_0$ , with the F branch of  $x_0$  leading directly to the terminal value 1. Conversely, in row 1 of the matrix, the columns differ, and hence the BDD node for  $y_0$  in the T branch of  $x_0$  is a fork\_node. In Fig. 2b, the bold path is for the assignment  $[x_0 \mapsto F, y_0 \mapsto T]$  for  $H_2[0, 1]$ . (Only the edge for  $x_0 \mapsto F$  is highlighted because the ply for  $y_0$  is skipped when  $x_0 \mapsto F$ .)

Fig. 2d shows the BDD for  $H_4$  under the interleaved-variable ordering  $\langle x_0, y_0, x_1, y_1 \rangle$ . The bold path is for the assignment  $[x_0 \mapsto F, y_0 \mapsto T, x_1 \mapsto F, y_1 \mapsto T]$ , which corresponds to  $H_4[0, 3]$ . (The path in the BDD only shows  $x_0 \mapsto F, x_1 \mapsto F$  because the plies for  $y_0$  when  $x_0 \mapsto F$ , and  $y_1$  when  $x_0 \mapsto F$  and  $x_1 \mapsto F$  are skipped.)

Fig. 2e shows that the Kronecker product  $H_4 = H_2 \otimes H_2$  corresponds to *stacking BDDs*—in essence, each terminal of the BDD for the left occurrence of  $H_2$  in " $H_2 \otimes H_2$ " is replaced by a copy of  $H_2$ . The BDD for  $H_4$  contains three occurrences of  $H_2$ : one in the  $\langle x_0, y_0 \rangle$  plies, and two in the  $\langle x_1, y_1 \rangle$  plies. The leftmost  $\langle x_1, y_1 \rangle$  occurrence (blue-dashed outline) accounts for the three occurrences of matrix  $H_2$  in the  $H_4$  matrix; the rightmost occurrence (green dashed-double-dotted outline) corresponds to the negated matrix  $-H_2$  in the lower-right corner of  $H_4$  (cf. Fig. 1). Consequently, one can construct a BDD for each member of  $\mathcal{H}$  by repeated stacking, doubling the number of plies each time, per  $H_{2^{i+1}} = H_{2^i} \otimes H_{2^i}$ , but only *tripling* the size with each such stacking operation (e.g.,  $H_8 = H_4 \otimes H_4$ has three copies of  $H_4$ , etc.). Consequently, the size of the BDD for  $H_{2^i}$  is  $O(3^i)$ .

Discussion. The decision tree for  $H_{2^i}$  has height  $2^i$ ,  $2^{2^i}$  leaves, and  $2^{2^i} - 1$  internal nodes. Thus, the size of the tree is double exponential in *i*. As observed above, the size of the BDD for  $H_{2^i}$  is  $O(3^i)$ , and hence, compared to decision trees, BDDs achieve exponential compression on  $\mathcal{H}$ .

In contrast, CFLOBDDs employ a different principle than stacking to account for Kronecker product. Looking ahead, this principle is explained in §3.4, and as we will see when we get to Fig. 6b, there is a CFLOBDD of size O(i) that encodes  $H_{2^i}$ . Consequently, CFLOBDDs achieve *double-exponential* compression on  $\mathcal{H}$ . Moreover, in §8, we show that this exponential separation is inherent: for every variable ordering, a BDD that represents  $H_{2^i}$  requires  $\Omega(2^i)$  nodes (Thm. 8.1).

In the remainder of the paper, detailed knowledge about BDDs is not essential. The primary purpose of the material that discusses BDDs is to show that CFLOBDDs offer something new, but that material is tangential to being able to understand the CFLOBDD algorithms that we give. The paper gives what is essentially a complete account of CFLOBDD operations and invariants, and we hope that it could be read by someone who knows little about BDDs. Nevertheless, additional knowledge about BDD internals could help readers appreciate the material in the paper. For background about how BDDs are implemented, the reader is referred to Brace et al. [10].

#### 3 CFLOBDDS

CFLOBDDs are a binary decision diagram inspired by BDDs, but the two data structures are based on different principles. A BDD is an acyclic finite-state machine (modulo ply-skipping), whereas a CFLOBDD is a particular kind of *single-entry, multi-exit, non-recursive, hierarchical finite-state* 

Fig. 3. (a) CFLOBDD for  $H_2$  using the variable ordering  $\langle x_0, y_0 \rangle$ . The bold path is for the assignment  $[x_0 \mapsto F, y_0 \mapsto T]$  for  $H_2[0, 1]$ . (b) Guide to the terminology introduced in Defn. 3.1.

*machine* (HFSM) [1]. This section describes the basic principles of CFLOBDDs, illustrating them via encodings of  $H_2$  and  $H_4$  with the variable orderings  $\langle x_0, y_0 \rangle$  and  $\langle x_0, y_0, x_1, y_1 \rangle$ , respectively.

*Intuition.* Before discussing the CFLOBDD data structure in detail, we give some intuition about the decomposition principle used in CFLOBDDs.

Consider a function  $f : \{0, 1\}^n \to [1 \dots m]$  over variables  $x_0, \dots, x_{n-1}$ . In the classical Shannon decomposition of f, one looks at the value of  $x_0$  and then derives two co-factors  $g_0 = f|_{x_0=0}$  and  $g_1 = f|_{x_0=1}$ , both of which are functions over variables  $x_1, \dots, x_{n-1}$ . Functions  $g_0$  and  $g_1$  can be combined to yield f by the identity  $f = \overline{x_0} \cdot g_0 + x_0 \cdot g_1$  (where  $\overline{x_0}$  denotes the complement of  $x_0$ , "·" denotes logical-and, and "+" denotes logical-or). (See [16, §4.2] for a precise definition of the generalization of the Shannon decomposition for MTBDDs.) The same decomposition can be carried out recursively on  $g_0$  and  $g_1$ , and OBDDs—whether reduced or not—exploit this decomposition by sharing common co-factors that arise in the different plies of the recursive decomposition.

The decomposition used in CFLOBDDs is different. The number of variables n is assumed to be a power of 2, and at each decomposition level the variables are divided into two halves:  $x_0, \ldots, x_{n/2-1}$  and  $x_{n/2}, \ldots, x_{n-1}$ .<sup>2</sup> Let  $g_0$  be the function of the first n/2 variables that maps them to  $[1 \ldots k]$ , where k is the number of equivalence classes of residual functions one has after the first n/2 variables of f are read. (k equals the number of nodes in the corresponding BDD for f at ply n/2.) For each  $i \in [1 \ldots k]$ ,  $g_i$  is the appropriate function over the remaining n/2 variables, which combined with  $g_0$  (based on index i), and an appropriate matching of returned values, yields f.<sup>3</sup> The representation allows sharing across all the functions  $g_0, g_1, \ldots, g_k$ . Moreover, the divide-the-variables-in-half decomposition is carried out recursively on  $g_0, g_1, \ldots, g_k$ , with mutual sharing of the decomposed functions that arise at all levels.

Rather than producing a DAG-structured data structure, as one has with BDDs, the divide-thevariables-in-half decomposition leads to a structure that resembles an HFSM (or, alternatively, the interprocedural control-flow graph for a non-recursive, multi-procedure program).

 <sup>&</sup>lt;sup>2</sup> For a Boolean function of *m* variables that is not a power of 2, one can pad the function with dummy Boolean variables
 to reach the next higher power of 2. Depending on the function, the user may choose to interleave the dummy variables
 among the "legitimate" variables or place them all at the end (or some combination of both). By this device, every Boolean
 function can be represented as a CFLOBDD. (See also the discussion in §4.2 of property (2).)

<sup>&</sup>lt;sup>341</sup> <sup>3</sup> We are being deliberately vague about how  $g_0, g_1, \ldots, g_k$  are combined, because the details are somewhat complicated. 342 See Defns. 3.1 and 4.1 for the precise definition.

#### 344 3.1 Matched Paths

The CFLOBDD representation of  $H_2$  consists of three *groupings*, shown as three ovals in Fig. 3a.<sup>4</sup> Each CFLOBDD grouping is associated with a given *level*. The two small ovals are at level 0 (labeled  $L_0$ ), and the large oval is at level 1 (labeled  $L_1$ ). There is an implicit hierarchical structure to the levels, and level-0 groupings are said to be *leaves* of the CFLOBDD. There are only two possible types of level-0 groupings:

- A level-0 grouping like the one at the upper right in Fig. 3a is called a *fork grouping*.
- A level-0 grouping like the one at the lower right in Fig. 3a is called a *don't-care grouping*.

The vertex at the top of each grouping is the grouping's *entry vertex*. The entry vertex of a level-0 grouping corresponds to a decision point: left branches are for F (or 0); right branches are for T (or 1). The vertices at the bottom of each grouping are called *exit vertices*; those in the middle of the level-1 grouping are called *middle vertices*.

In matrix  $H_2$ , each entry is either 1 or -1. Each assignment over  $\langle x_0, y_0 \rangle$  corresponds to a special kind of path in Fig. 3a that leads to either 1 or -1. Each such path starts from the entry vertex of the level-1 grouping, making "decisions" for the next variable in sequence each time the entry vertex of a level-0 grouping is encountered.

Fig. 3a illustrates the key principle behind CFLOBDDs-namely, the use of a matching condition 361 on paths. The bold path is for the assignment  $[x_0 \mapsto F, y_0 \mapsto T]$ , which corresponds to  $H_2[0, 1]$ . 362 The path starts at the level-1 grouping's entry vertex and goes to the entry vertex of the level-0 363 fork grouping via a solid edge (-); takes the left branch of the fork grouping (corresponding to 364  $x_0 \mapsto F$ ; and leaves the fork grouping via a solid edge (-), reaching the leftmost of the middle 365 vertices of the level-1 grouping. The path then goes to the entry vertex of the level-0 don't-care 366 grouping via a dashed-double-dotted edge  $(- \cdot -)$ ; takes the right branch of the don't-care grouping 367 (corresponding to  $y_0 \mapsto T$ ); and leaves via a dashed-double-dotted edge  $(- \cdot -)$ , reaching the 368 leftmost exit vertex of the level-1 grouping, which is connected to the terminal value 1 (the value 369 of  $H_2[0, 1]$ ). A pair of incoming/outgoing edges of a grouping, such as the pairs of (i) black solid 370 edges, and (ii) green dashed-double-dotted edges in the bold path in Fig. 3a, are said to be matched. 371 The bold path itself is called a *matched path*. This example illustrates the following principle: 372

# **Matched-Path Principle**. When a path follows an edge that returns to level i from level i - 1, it must follow an edge that matches the closest preceding edge from level i to level i - 1.

375 Formally, the matched-path principle can be expressed as a condition that-for a path to be 376 matched—the word spelled out by the labels on the edges of the path must be a word in a certain 377 context-free language [69]. (This idea is the origin of "CFL" in "CFLOBDD".) One way to formalize 378 the condition is to label each edge from level *i* to level i - 1 with an open-parenthesis symbol of 379 the form " $(_b$ ", where b is an index that distinguishes the edge from all other edges to any entry 380 vertex of any grouping of the CFLOBDD. (In particular, suppose that there are NumConnections 381 such edges, and that the value of b runs from 1 to NumConnections.) Each return edge that runs 382 from an exit vertex of the level i - 1 grouping back to level i, and corresponds to the edge labeled 383 "( $_b$ ", is labeled ") $_b$ ". Each path in a CFLOBDD then generates a string of parenthesis symbols formed 384 by concatenating, in order, the labels of the edges on the path. (Unlabeled edges in the level-0 385 groupings are ignored in forming this string.) A path in a CFLOBDD is called a matched-path iff 386 the path's word is in the language L(matched) of balanced-parenthesis strings generated by 387

388 389

373

374

matched  $\rightarrow \epsilon \mid$  matched matched  $\mid (_b \text{ matched })_b \quad 1 \le b \le \text{NumConnections}$  (1)

391 392

390

350

351

<sup>&</sup>lt;sup>4</sup> Groupings are represented in memory as a kind of node structure, but we will use "nodes" solely for decision trees and BDDs. Groupings are depicted as ovals, and the dots inside will be referred to as "vertices."

Only *matched*-paths that start at the entry vertex of the CFLOBDD's highest-level grouping and end at a terminal value are considered in interpreting a CFLOBDD.

In figures in the paper, we use black solid (-), blue dashed (- - -), red short-dashed (- - -), purple dashed-dotted (-  $\cdot$  -), and green dashed-double-dotted (-  $\cdot$  -) edges, in the indicated colors, rather than attaching explicit labels to edges. To reduce the number of colors used, we sometimes re-use colors in a given figure; however, it should still be clear which pairs of edges match.

The matched-path principle allows a given grouping to play multiple roles during the evaluation of a Boolean function. In particular, the level-0 groupings are shared, and thus are used to interpret *different variables at different places in a matched path through a CFLOBDD*. For example, the level-0 fork grouping in Fig. 3a is used to interpret (i)  $x_0$  (when "called" via the black solid edge), and (ii)  $y_0$  (when "called" via the blue dashed edge, which happens when  $x_0 \mapsto T$ ).<sup>5</sup> The edge-matching condition is important because the black solid return edges lead to the level-1 grouping's middle vertices, whereas the blue dashed return edges lead to the level-1 grouping's exit vertices.

In Fig. 3a, the fork grouping is labeled with  $x_0$  and  $y_0$ , and the don't-care grouping with  $y_0$ . In general, however, the level-0 groupings interpret *different variables at different places in a matched path*, in accordance with the following principle:

**Contextual-Interpretation Principle**. A level-0 grouping is not associated with a specific Boolean variable. Instead, the variable that a level-0 grouping refers to is determined by context: the n<sup>th</sup> level-0 grouping visited along a matched path is used to interpret the n<sup>th</sup> Boolean variable.

The reader might be worried by the fact that Fig. 3a contains cycles. That is, if one ignores the ovals in Fig. 3a, as well as the distinctions among solid, dashed, and dashed-double-dotted edges, one is left with a cyclic graph: there is a cycle that starts at the rightmost middle vertex of the level-1 grouping, follows the blue dashed edge (--) to the entry vertex of the level-0 fork-grouping, takes the right branch, and returns along the black solid edge (-) to the rightmost middle vertex of the level-1 grouping. However, that path is not a matched path, and is excluded from consideration.

#### 3.2 CFLOBDD Requirements

In designing CFLOBDDs, the goal is to meet the following five requirements:

- (1) Soundness: Every level-k CFLOBDD represents a decision tree of height  $2^k$  and size  $2^{2^k}$
- (2) Completeness: each decision tree of height  $2^k$  and size  $2^{2^k}$  can be encoded as a level-k CFLOBDD
- (a) Computer and a construction are considered as a level k of HOBDE (3) Best-case double-exponential compression: in the best case, a decision tree of height  $2^k$  and size  $2^{2^k}$  can be encoded as a level-k CFLOBDD of size k
  - (4) Canonicity: CFLOBDDs are a canonical representation of Boolean functions
  - (5) Computational efficiency: operations run in time polynomial in the size of the CFLOBDD

These requirements are similar to those for BDDs, but with double-exponential parameters—rather than single-exponential parameters—in Requirements (1)–(3). To satisfy these more stringent requirements, we define a data structure that is quite different from BDDs (see §3.3 and §4.1). Requirements (1) and (3) are established in §3.3.4 and §3.5.2, respectively. Requirements (2) and (4) are established in §4 and Appendix §C. Requirement (5) is addressed in §5 and §6; in particular, Tab. 1 at the beginning of §6 lists the fourteen main operations on CFLOBDDs and the asymptotic running times of the algorithms that we give for the operations.

 <sup>&</sup>lt;sup>439</sup> <sup>5</sup>The term "call" is by analogy with how matched paths model the actions of procedure calls in graphs used for interprocedural dataflow analysis [55, 58], interprocedural slicing [30], and model checking hierarchical state machines [9, §5].

#### 442 3.3 CFLOBDDs Defined, Part I: Basic Structure

443 Our formal definition of CFLOBDDs is given in two parts: Defn. 3.1 (below) and Defn. 4.1 (§4.1). 444 Defn. 3.1 defines the basic structure of CFLOBDDs, whose various elements are depicted in Fig. 3b. 445 Defn. 4.1 imposes some additional structural invariants to ensure that CFLOBDDs provide a 446 canonical representation of Boolean functions. Much about CFLOBDDs can be understood just 447 from Defn. 3.1, so we postpone introducing the structural invariants until we address canonicity 448 in §4. Where necessary, we distinguish between mock-CFLOBDDs (Defn. 3.1) and CFLOBDDs 449 (Defn. 4.1), although we typically drop the qualifier "mock-" when there is little danger of confusion. 450 Fig. 3b illustrates Defn. 3.1 using the CFLOBDD that represents Hadamard matrix  $H_2$ . 451

<sup>452</sup> *Definition 3.1 (Mock-CFLOBDD; see Fig. 3b).* A *mock-CFLOBDD* at level k is a hierarchical structure <sup>453</sup> made up of some number of *groupings*, of which there is one grouping at level k, and at least one at <sup>454</sup> each level 0, 1, ..., k - 1. The grouping at level k is the *head* of the mock-CFLOBDD. A grouping is <sup>455</sup> a collection of vertices and edges (to other groupings), with the structure described below.

Each grouping  $g_i$  at level  $0 \le i \le k$  has a unique *entry vertex*, which is disjoint from  $g_i$ 's non-empty set of *exit vertices*.

If i = 0,  $g_i$  is either a *fork grouping* or a *don't-care grouping*, as depicted in the upper right and lower right of Fig. 3b, respectively. The entry vertex of a level-0 grouping corresponds to a decision point: left branches are for *F* (or 0); right branches are for *T* (or 1). A don't-care grouping has a single exit vertex, and the edges for the left and right branches both connect the entry vertex to the exit vertex. A fork grouping has two exit vertices: the entry vertex's left and right branches connect the entry vertex to the first and second exit vertices, respectively.

464 If  $i \ge 1$ ,  $q_i$  has a further disjoint set of *middle vertices*. We assume that both the middle vertices and the exit vertices are associated with some fixed, known total order (i.e., the sets of middle 465 vertices and exit vertices could each be stored in an array). Moreover,  $q_i$  has an A-connection edge 466 that, from  $q_i$ 's entry vertex, "calls" a level-*i*-1 grouping  $a_{i-1}$ , along with a set of matching return 467 *edges*; each return edge from  $a_{i-1}$  connects one of the exit vertices of  $a_{i-1}$  to one of the middle 468 469 vertices of  $g_i$ . In addition, for each middle vertex  $m_i$ ,  $g_i$  has a *B*-connection edge that "calls" a level-*i*-1 grouping  $b_i$ , along with a set of matching *return edges*; each return edge from  $b_i$  connects one of 470 471 the exit vertices of  $b_i$  to one of the exit vertices of  $q_i$ .

If i = k,  $g_k$  has a set of value edges that connect each exit vertex of  $g_k$  to a *terminal value*.

3.3.1 An Object-Oriented Pseudo-Code. In later parts of the paper, we state algorithms using an
object-oriented pseudo-code. In accordance with the terminology introduced above, the basic
classes that are used for representing multi-terminal CFLOBDDs are defined in Fig. 4a: Grouping,
InternalGrouping, DontCareGrouping, ForkGrouping, and CFLOBDD. More details about the notation used in our pseudo-code can be found in Appendix §A.

Fig. 4c shows how the CFLOBDD from Fig. 3a is represented as an instance of class CFLOBDD. 480 There are no entry, middle, and exit vertices as such. Instead, a pointer to a Grouping object 481 serves as the object's entry vertex. Numbers in the range [1..numberOfBConnections] serve as 482 middle vertices, and numbers in the range [1..numberOfExits] serve as exit vertices. In the level-483 1 InternalGrouping in Fig. 4c, one can see that a ReturnTuple—which holds a sequence of 484 return-edge targets—is associated with each outgoing AConnection or BConnection edge. This 485 organization facilitates implementing the matched-path principle: when a level-l+1 grouping  $q_1$ 486 "calls" level-l grouping  $q_2$ , there is an associated ReturnTuple  $rt_1$  (stored in  $q_1$ ); a matched path 487 starting at the entry of  $q_2$  leads to some exit-vertex index i of  $q_2$ ; and  $rt_1[i]$  holds the target in  $q_1$  of 488 the matching return edge. 489

Fig. 4. (a) Datatypes for Grouping, InternalGrouping, DontCareGrouping, ForkGrouping, and CFLOBDD. (b) The CFLOBDD for  $H_2$  (repeated from Fig. 3a). (c) An instance of class CFLOBDD that represents  $H_2$ .

Similarly, there are no explicit edges in DontCareGrouping and ForkGrouping objects. Instead, the decision taken at the level-0 grouping's entry vertex selects the appropriate exit-vertex index, which is used to index into a ReturnTuple of the "calling" level-1 InternalGrouping.

3.3.2 *Rationale.* The rationale behind the terminology introduced in Defn. 3.1, Fig. 3b, and Fig. 4a goes back to the Matched-Path Principle. In particular, each InternalGrouping object g at level i > 0 represents a family of matched paths. A traversal of a matched path from g's entry vertex to an exit vertex of g uses the fields of g (Fig. 4a) in the following order, which mimics the form of the grammar for matched paths from Eqn. (1):

```
matched(at level i) = AConnection matched(at level i-1) AReturnTuple[\cdot] BConnections matched(at level i-1) BReturnTuples[\cdot] (2)
```

*3.3.3 Inductive Arguments about CFLOBDDs.* To be able to make inductive arguments about CFLOBDDs, it is convenient to introduce one additional bit of terminology:

*Definition 3.2 (Mock-proto-CFLOBDD).* A *mock-proto-CFLOBDD* at level *i* is a grouping at level *i*, together with the lower-level groupings to which it is connected (and the connecting edges). In other words, a mock-proto-CFLOBDD has the following recursive structure:

Meghana Aparna Sistla, Swarat Chaudhuri, and Thomas Reps

12

541

544

545 546

556 557

- a mock-proto-CFLOBDD at level 0 is either a fork grouping or a don't-care grouping
  - a mock-proto-CFLOBDD at level *i* is headed by a grouping at level *i* whose
- A-connection edge and associated return edges "call" a level-(*i*-1) mock-proto-CFLOBDD,
   and
  - B-connection edges and their associated return edges "call" some number of level-(*i*-1) mock-proto-CFLOBDDs.

The difference between a proto-CFLOBDD and a CFLOBDD is that the exit vertices of a proto-CFLOBDD have not been associated with specific values. One cannot argue inductively in terms of CFLOBDDs because its constituents are proto-CFLOBDDs, not full-fledged CFLOBDDs. Thus, to prove that some property holds for a CFLOBDD, there will typically be an inductive argument to establish a property of the proto-CFLOBDD headed by the outermost grouping of the CFLOBDD, with an additional argument about the CFLOBDD's value edges and terminal values.

One example of an inductive argument allows us to establish the number of times D(i) that each matched path in a level-*i* proto-CFLOBDD reaches a decision vertex—i.e., the entry vertex of a level-0 grouping. In particular, D(i) is described by the following recurrence relation:

$$D(0) = 1 D(i) = D(i-1) + D(i-1), (3)$$

which has the solution  $D(i) = 2^i$ .

3.3.4 Soundness and an Operational Semantics. Eqn. (3) allows us to establish Requirement (1) from §3.2. Eqn. (3) has the solution  $D(i) = 2^i$ , so each matched path from the entry vertex of a level-*k* CFLOBDD passes through the entry vertex of a level-0 grouping exactly  $2^k$  times before reaching a terminal value  $v \in V$ , for some value domain *V*. Consequently, each (multi-terminal) CFLOBDD represents a function in  $\{T, F\}^{2^k} \rightarrow V$ —i.e., the same set of functions that decision trees represent.

We can also use the Contextual-Interpretation Principle to obtain an operational semantics for (mock-)CFLOBDDs, given as Alg. 1. This algorithm is a divide-order-and-conquer algorithm that specifies how to interpret a given CFLOBDD n with respect to a given Assignment a to the Boolean variables. (We assume that an Assignment is given as an array of Booleans, whose entries—starting at index-position 1—are the values of the successive variables.)

571 Subroutine InterpretGrouping performs a recursive traversal over n, following AConnections, 572 BConnections, and return edges. When a level-0 grouping is reached, the value of the current 573 Boolean variable is consulted (line [8], in the case of a ForkGrouping), or ignored (line [9], in 574 the case of a DontCareGrouping). (Line [10] can be ignored for now; it is an optimization that is 575 discussed in §3.5.2.) In lines [13] and [14], Assignment a is split in half: the Boolean values in the 576 first half are interpreted during the traversal of g's AConnection (line [13]); the values in the second 577 half are interpreted during the traversal of one of g's BConnections (line [14]), selected according 578 to the value i obtained in line [13] from the call on InterpretGrouping() with g's AConnection. 579

3.3.5 Multiple Middle Vertices and Exit Vertices. In a Boolean-valued CFLOBDD, the outermost grouping has at most two exit vertices, and these are mapped to  $\{F, T\}$ . In a multi-terminal CFLOBDD, there can be an arbitrary number of exit vertices, which are mapped to values drawn from some finite set of values V. Fig. 3a is a multi-terminal CFLOBDD; the level-1 grouping has two exit vertices that are mapped to 1 and -1.

Groupings that have more than two exit vertices naturally arise in the interior groupings of CFLOBDDs—even in Boolean-valued CFLOBDDs. For instance, a level-*i*-1 grouping used as an *A*-connection can have more than two exit vertices, in which case the "calling" level-*i* grouping

would have more than two middle vertices. Such multi-terminal groupings can arise in both *A*-connections and *B*-connections. Fig. 5 shows a Boolean-valued CFLOBDD that contains a level-1

636 637

grouping that has three exit vertices. The grouping is the A-connection of the outermost grouping(at level 2), which thus has three middle vertices.

#### 641 3.4 Encoding $H_4$ and Other Members of $\mathcal{H}$ with a CFLOBDD

Fig. 6a shows the CFLOBDD representation of Hadamard matrix  $H_4$  with the variable ordering  $\langle x_0, y_0, x_1, y_1 \rangle$ . In  $H_4$ , the level-1 proto-CFLOBDD is identical to the level-1 proto-CFLOBDD in  $H_2$ (cf. Fig. 3a and Fig. 6a). Moreover, in  $H_4$  the A-connection call and both B-connection calls are to the level-1  $H_2$  lookalike.

Consider how Fig. 6a encodes  $H_4[0,3] = 1$ . The value is obtained by evaluating the assignment 646  $[x_0 \mapsto F, y_0 \mapsto T, x_1 \mapsto F, y_1 \mapsto T]$ , following the matched path highlighted in bold. The path 647 starts from the level-2 grouping's entry vertex. It goes to the level-1 grouping's entry vertex, where 648 649  $[x_0 \mapsto F, y_0 \mapsto T]$  is interpreted as for  $H_2$ -i.e., the first occurrence of  $H_2$  in " $H_2 \otimes H_2$ "-in this case, 650 returning to the leftmost middle vertex of the level-2 grouping. At this point, the path follows the red dashed edge back to the level-1 grouping's entry vertex, where  $[x_1 \mapsto F, y_1 \mapsto T]$  is interpreted 651 652 as for  $H_2$ —the second occurrence of  $H_2$  in " $H_2 \otimes H_2$ ." The path then follows the matching red dashed 653 return edge to the leftmost exit vertex of the level-2 grouping, and reaches terminal value 1.

To create  $H_4$  using  $H_2$ , we introduced a level-2 grouping that makes one A-connection and two B-connection "calls" to the level-1  $H_2$  lookalike, and thus each matched path makes two sequential invocations of  $H_2$ . This pattern produces the same effect as the *stacking of plies* in decision trees and BDDs. However, rather than *tripling* the size of the data structure (as with BDDs—see Fig. 2e), the ability of CFLOBDDs to reuse parts of a data structure via a "call" means that there is only a *constant-size increase* in going from from  $H_2$  to  $H_4$ : one grouping with five vertices and nine edges (one A-connection, two B-connections, and six return edges).

The continuation of this pattern gives an inductive construction of the CFLOBDDs for the other members of  $\mathcal{H}$ . Given the level-*i* CFLOBDD for  $H_{2^i}$ ,  $i \ge 2$ ,  $H_{2^{i+1}} = H_{2^i} \otimes H_{2^i}$  is created by introducing a new outermost grouping at level i + 1, again with five vertices and nine edges. (See Fig. 6b.) The same pattern of "calls" is used for the A- and B-connections and their return edges: each matched path makes two sequential invocations of the level-*i* grouping for  $H_{2^i}$ . In other words,

**Sequential-Invocation Principle**. A Kronecker product  $P \otimes Q$  can be represented economically in a CFLOBDD by a grouping at level i + 1 whose A-connection "calls" the level-i proto-CFLOBDD for P and all of whose B-connection "calls" are to the level-i CFLOBDD for Q.

#### 3.5 Reuse of Groupings and Compression of Boolean Functions

The reason CFLOBDDs can represent certain Boolean functions in a highly compressed fashion is the reuse of groupings that the matched-path and sequential-invocation principles enable.

3.5.1 Growth of Number of Paths with Level. Let P(i) be the number of matched paths in a proto-CFLOBDD at level *i*. Each level-0 grouping has two paths, so P(0) = 2. In a grouping *g* at level  $i \ge 1$ , each matched path through the A-connection's level-(i-1) proto-CFLOBDD reaches a middle vertex of *g*, where it is routed through the level-(i-1) proto-CFLOBDD of the vertex's *B*-connection. Let  $A_j(i-1)$  be the number of matched paths through *g*'s A-connection proto-CFLOBDD to the *j*<sup>th</sup> middle vertex of *g*. Thus, P(i) satisfies the following recurrence equation:

$$P(0) = 2 P(i) = \sum_{i} A_{i}(i-1) \cdot P(i-1). (4)$$

The total number of matched paths through *g*'s A-connection proto-CFLOBDD is P(i - 1), so  $\sum_j A_j(i - 1) = P(i - 1)$ , and hence Eqn. (4) can be rewritten as  $P(i) = P(i - 1) \cdot P(i - 1)$ , which has the solution  $P(i) = 2^{2^i}$ .

(a) The CFLOBDD representation of  $H_4$  with the interleaved-variable ordering  $\langle x_0, y_0, x_1, y_1 \rangle$ . The matched path for  $[x_0 \mapsto F, y_0 \mapsto T, x_1 \mapsto F, y_1 \mapsto T]$ , which

corresponds to  $H_4[0,3]$ , is shown in bold.

Fig. 6. Construction of successively larger members of  $\mathcal{H} = \{H_{2^i} \mid i \ge 1\}$ . At level *i*+1, each matched path makes two sequential invocations of the level-*i* grouping (for  $H_{2^i}$ ), thereby creating  $H_{2^{i+1}} = H_{2^i} \otimes H_{2^i}$ .

Fig. 7. The family of no-distinction proto-CFLOBDDs.

**Growth in Paths**. The number of matched paths in a CFLOBDD is squared with each increase in level by 1. Consequently, a CFLOBDD at level i has  $2^{2^i}$  matched paths.

3.5.2 Best-Case Compression: No-Distinction Proto-CFLOBDDs. Fig. 7a, 7b, and 7c show the first three members of a family of proto-CFLOBDDs that often arise as sub-structures of CFLOBDDs: the single-entry/single-exit proto-CFLOBDDs of levels 0, 1, and 2, respectively. Because every matched path through each of these structures ends up at the unique exit vertex of the highest-level grouping, there is no "decision" to be made during each visit to a level-0 grouping. In essence, as we work our way through such a structure during the interpretation of an assignment, the value assigned to each argument variable makes no difference.

We call this family the *no-distinction proto-CFLOBDDs*. Fig. 7d illustrates the structure of a no-distinction proto-CFLOBDD at an arbitrary level k > 0, which continues the pattern that one

sees in the level-1 and level-2 structures: the level-*k* grouping has a single middle vertex, and both its *A*-connection and its one *B*-connection are to the no-distinction proto-CFLOBDD for level k - 1. Moreover, because the no-distinction proto-CFLOBDD at level *k* shares all but one constant-sized grouping with the no-distinction proto-CFLOBDD at level k - 1, each additional level costs only a constant amount of additional space. Thus, the no-distinction proto-CFLOBDD at level *k* is of size O(k), and hence the no-distinction proto-CFLOBDDs exhibit double-exponential compression.

The Boolean-valued CFLOBDD for the constant function  $\lambda x_0, x_1, \ldots, x_{2^k-1}$ . *F* is merely the CFLOBDD in which a value edge connects the (one) exit vertex of the no-distinction proto-CFLOBDD at level *k* to *F*. Likewise, in the constant function  $\lambda x_0, x_1, \ldots, x_{2^k-1}$ . *T*, the value edge connects the exit vertex of the no-distinction proto-CFLOBDD at level-*k* to *T*. Thus, as the number of Boolean variables increases, the best-case growth of CFLOBDDs compares with the growth of decision trees as follows:

	Boolean	Number		Decision tre	ees		CFLOBDDs	(best case)	
	vars.	of paths	height	#nodes	#edges	height <sup>a</sup>	#groupings	#vertices	#edges
-	1	2	1	3	2	0	1	2	3
	2	4	2	7	6	1	2	5	7
	4	16	4	31	30	2	3	8	11
	8	256	8	511	510	3	4	11	15
	÷	:	÷	:	:	:	÷	÷	÷
	$2^k$	$2^{2^{k}}$	$2^k$	$2 \cdot 2^{2^k} - 1$	$2 \cdot 2^{2^k} - 2$	k	k + 1	3k + 2	4k + 3

<sup>a</sup>The height of a CFLOBDD is the level of the outermost grouping.

The best-case CFLOBDD size—whether measured in the number of groupings, vertices, or edges grows linearly with the level of the outermost grouping, which is *logarithmic* in the number of Boolean variables. In contrast, decision trees grow *exponentially* in the number of Boolean variables. These observations show that Requirement (3) from §3.2 is met: in the best case, a decision tree of height  $2^k$  and size  $2^{2^k}$  can be encoded as a level-*k* CFLOBDD of size *k*.

Remark. Because the family of no-distinction proto-CFLOBDDs is so compact, in designing 765 CFLOBDDs we did not feel the need to mimic the "ply-skipping transformation" of Reduced 766 OBDDs (ROBDDs) [10, 11], in which "don't-care" nodes are removed from the representation. In 767 ROBDDs, in addition to reducing the size of the data structure, the chief benefit of ply-skipping 768 is that operations can skip over levels in portions of the data structure in which no distinctions 769 among variables are made. Essentially the same benefit is obtained by having the algorithms 770 that process CFLOBDDs carry out appropriate special-case processing when no-distinction proto-771 CFLOBDDs are encountered. Such processing is carried out, for instance, in line [10] of Alg. 1: in 772 InterpretCFLOBDD(), when Grouping g is the head of a NoDistinctionProtoCFLOBDD, both g 773 and the entire Assignment a can be ignored because g has only a single exit vertex. 774

Whereas in the best case, the CFLOBDD for a function f can be double-exponentially smaller 775 than the decision tree for f, ROBDDs are incapable of such a degree of compression. Quasi-reduced 776 BDDs are the version of BDDs in which don't-care nodes are not removed (i.e., plies are not skipped), 777 and thus all paths from the root to a terminal value have length *n*, where *n* is the number of variables. 778 The size of a quasi-reduced BDD is at most a factor of n + 1 larger than the size of the corresponding 779 ROBDD [64, Thm. 3.2.3]. Thus, although ROBDDs can give better-than-exponential compression 780 compared to decision trees, what one has is not double-exponential compression: at best, it is 781 linear compression of exponential compression. Moreover, in §8 we show that the CFLOBDD for a 782 function *q* can be exponentially smaller than *any* ROBDD for *q*. 783

3.5.3 Asymptotic Best-Case Compression. Consider a family of functions  $F = \{f_i \mid i \ge 0\}$ , where 785 the  $i^{th}$  member has  $2^{j}$  Boolean arguments. The following property is a sufficient condition for 786 the sizes of the CFLOBDDs for members of F to grow linearly in the level i, and therefore exhibit 787 788 double-exponential compression compared to decision trees:

- (1) There exists a family of functions  $G = \{g_j \mid j \ge 0\}$  that grows linearly in the level *i*.<sup>6</sup>
- (2) There exists a level *m* such that, for all levels  $i \ge m$ ,
  - (a) the number of vertices in the level-*i* grouping of  $f_i$  is a constant independent of *i*
  - (b) the level-*i* grouping of  $f_i$  makes "procedure calls" only to (i) the level-(*i*-1) grouping used in the CFLOBDD for  $f_{i-1}$ , and (ii) level-(*i*-1) groupings used in the CFLOBDD for  $q_{i-1}$ .<sup>7</sup>

In such a case, the CFLOBDD for each  $f_i$  is double-exponentially smaller than the decision tree for  $f_i$ —i.e., of size O(i) rather than  $O(2^{2^i})$ . As shown in Fig. 6b, the family of Hadamard matrices  $\mathcal{H}$ meets the above conditions.

Moreover, in all cases encountered to date, it is possible to give an explicit algorithm for constructing the  $i^{th}$  member of F, where the algorithm runs in time O(i) and uses at most O(i) space.

No information-theoretic limit is being violated here. Not all families of functions can be represented with CFLOBDDs in which each level has a constant number of groupings, each of constant size-and thus, not every function over Boolean-valued arguments can be represented in such a compressed fashion. However, the potential benefit of CFLOBDDs is that, just as with BDDs, there may turn out to be enough regularity in problems that arise in practice that CFLOBDDs stay of manageable size. Moreover, double-exponential compression (or any kind of super-exponential compression) could allow problems to be completed much faster (due to the smaller-sized structures involved), or allow far larger problems to be addressed than has been possible heretofore.

#### CANONICITY 4

In this section, we impose some further structural restrictions on proto-CFLOBDDs and CFLOBDDs that go beyond the ideas illustrated earlier (§4.1). We then discuss how to establish that CFLOBDDs are a canonical representation of Boolean functions (§4.2 and Appendix §C).

#### **CFLOBDDs Defined, Part II: Additional Structural Invariants** 4.1

As described in §3, the structure of a mock-CFLOBDD consists of different groupings organized into levels, which are connected by edges in a particular fashion. In this section, we describe additional structural invariants that are imposed on CFLOBDDs, which go beyond the basic hierarchical structure that is provided by the entry vertex, A-Connection, middle vertices, B-Connections, return edges, and exit vertices of a grouping.

Most of the structural invariants concern the organization of what we call return tuples (following 820 the terminology introduced in Fig. 4). For a given A-connection edge or B-connection edge c from grouping  $q_i$  to  $q_{i-1}$ , the return tuple  $rt_c$  associated with c consists of the sequence of targets of 822 return edges from  $q_{i-1}$  to  $q_i$  that correspond to c (listed in the order in which the corresponding 823 exit vertices occur in  $q_{i-1}$ ). Similarly, the sequence of targets of value edges that emanate from the 824 exit vertices of the highest-level grouping q (listed in the order in which the corresponding exit 825 vertices occur in *q*) is called the CFLOBDD's value tuple. 826

Return tuples represent mapping functions that map exit vertices at one level to middle vertices 827 or exit vertices at the next greater level. Similarly, value tuples represent mapping functions that 828 map exit vertices of the highest-level grouping to terminal values. In both cases, the  $i^{th}$  entry of the 829

<sup>830</sup> <sup>6</sup>The family of no-distinction proto-CFLOBDDs from Fig. 7 is one such family G.

<sup>831</sup> <sup>7</sup>Condition 2b can be generalized so that  $f_i$  can "call" the (*i*-1) groupings used in the CFLOBDDs for some constant number of function families  $G_1, G_2, \ldots, G_l$  that each grow linearly in the level *i*. 832

tuple indicates the element that the *i*<sup>th</sup> exit vertex is mapped to. Because the middle vertices and
exit vertices of a grouping are each arranged in some fixed known order, and hence can be stored
in an array, it is often convenient to assume that each element of a return tuple is simply an index
into such an array. For example, in Fig. 5,

- The return tuple associated with the 1<sup>st</sup> B-connection of the upper level-1 grouping is [1, 2].
- The return tuple associated with the  $2^{nd}$  *B*-connection of the upper level-1 grouping is [2, 3].
- The return tuple associated with the *A*-connection of the level-2 grouping is [1, 2, 3].
  - The value tuple associated with the CFLOBDD is the 2-tuple [*F*, *T*].

*Rationale.* The structural invariants are designed to ensure that—for a given order on the Boolean
variables—each Boolean function has a unique, canonical representation as a CFLOBDD. In reading
Defn. 4.1 below, it will help to keep in mind that the goal of the invariants is to force there to
be a *unique* way to fold a given decision tree into a CFLOBDD that represents the same Boolean
function. The decision-tree folding method is discussed in §4.2 and Appendix §C, but the main
characteristic of the folding method is that it works greedily, left to right. This directional bias
shows up in structural invariants 1, 2a, and 2b.

We can now complete the formal definition of a CFLOBDD.

Definition 4.1 (Proto-CFLOBDD and CFLOBDD). A proto-CFLOBDD *n* is a mock-proto-CFLOBDD (Defns. 3.1 and 3.2) in which every grouping/proto-CFLOBDD in *n* satisfies the *structural invariants* given below. In particular, let *c* be an *A*-connection edge or *B*-connection edge from grouping  $g_i$  to  $g_{i-1}$ , with associated return tuple  $rt_c$ .

- (1) If *c* is an *A*-connection, then  $rt_c$  must map the exit vertices of  $g_{i-1}$  one-to-one, and in order, onto the middle vertices of  $g_i$ : Given that  $g_{i-1}$  has *k* exit vertices, there must also be *k* middle vertices in  $g_i$ , and  $rt_c$  must be the *k*-tuple [1, 2, ..., k]. (That is, when  $rt_c$  is considered as a map on indices of exit vertices of  $g_{i-1}$ ,  $rt_c$  is the identity map.)
  - (2) If *c* is the *B*-connection edge whose source is middle vertex j + 1 of  $g_i$  and whose target is  $g_{i-1}$ , then  $rt_c$  must meet two conditions:
  - (a) It must map the exit vertices of  $g_{i-1}$  one-to-one (but not necessarily onto) the exit vertices of  $g_i$ . (That is, there are no repetitions in  $rt_c$ .)
- (b) It must "compactly extend" the set of exit vertices in g<sub>i</sub> defined by the return tuples for the previous *j B*-connections: Let rt<sub>c1</sub>, rt<sub>c2</sub>, ..., rt<sub>cj</sub> be the return tuples for the first *j B*-connection edges out of g<sub>i</sub>. Let S be the set of indices of exit vertices of g<sub>i</sub> that occur in return tuples rt<sub>c1</sub>, rt<sub>c2</sub>, ..., rt<sub>cj</sub>, and let n be the largest value in S. (That is, n is the index of the rightmost exit vertex of g<sub>i</sub> that is a target of any of the return tuples rt<sub>c1</sub>, rt<sub>c2</sub>, ..., rt<sub>cj</sub>.) If S is empty, then let n be 0.
- Now consider  $rt_c$  (=  $rt_{c_{j+1}}$ ). Let R be the (not necessarily contiguous) sub-sequence of  $rt_c$ whose values are strictly greater than n. Let m be the size of R. Then R must be exactly the sequence [n + 1, n + 2, ..., n + m].
  - (3) While a proto-CFLOBDD may be used as a substructure more than once (i.e., a proto-CFLOBDD may be *pointed to* multiple times), a proto-CFLOBDD never contains two separate *instances* of equal proto-CFLOBDDs.<sup>8</sup>

, Vol. 1, No. 1, Article . Publication date: December 2023.

 <sup>&</sup>lt;sup>8</sup> Equality on proto-CFLOBDDs is defined inductively on their hierarchical structure in the obvious manner. Two CFLOBDDs
 are equal when (i) their proto-CFLOBDDs are equal, and (ii) their value tuples are equal. §5.1 discusses how hash-consing
 [23] can be used to enforce the invariant that only a single representative CFLOBDD/proto-CFLOBDD exists for each
 equivalence class of CFLOBDD/proto-CFLOBDD values. However, when we wish to consider the possibility that *multiple* data-structure instances exist that are equal—as we do shortly in §4.2—we say that such structures are "isomorphic" or
 "equal (up to isomorphism)."

- (4) For every pair of *B*-connections *c* and *c'* of grouping  $g_i$ , with associated return tuples  $rt_c$  and  $rt_{c'}$ , if *c* and *c'* lead to level i - 1 proto-CFLOBDDs, say  $p_{i-1}$  and  $p'_{i-1}$ , such that  $p_{i-1} = p'_{i-1}$ , then the associated return tuples must be different (i.e.,  $rt_c \neq rt_{c'}$ ).
- A *CFLOBDD* at level k is a mock-CFLOBDD at level k for which
  - (5) The grouping at level k heads a proto-CFLOBDD.
- (6) The grouping at refer index a prote or DODDD.
  (6) The value tuple associated with the grouping at level k maps each exit vertex to a *distinct* value.

Fig. 8 illustrates structural invariants 1, 2a, 2b, 3, 4, and 6. In each case, a mock-proto-CFLOBDD
 that violates one of the structural invariants is shown on the left, and an equivalent proto-CFLOBDD
 that satisfies the structural invariants is shown on the right.

- <sup>894</sup> The CFLOBDD from Fig. 5 also illustrates the structural invariants.
  - The level-1 grouping pointed to by the *A*-connection of the level-2 grouping has three exit vertices. These are the targets of two return tuples from the uppermost level-0 fork grouping. Note that the blue dashed lines in this proto-CFLOBDD correspond to *B*-connection 1 and *rt*<sub>1</sub>, whereas the red short-dashed lines correspond to *B*-connection 2 and *rt*<sub>2</sub>.

In the case of  $rt_1$ , the set *S* mentioned in structural invariant 2b is empty; therefore, n = 0 and  $rt_1$  is constrained by structural invariant 2b to be [1, 2].

- In the case of  $rt_2$ , the set *S* is {1, 2}, and therefore n = 2. The first entry of  $rt_2$ , namely 2, falls within the range [1..2]; the second entry of  $rt_2$  lies outside that range and is thus constrained to be 3. Consequently,  $rt_2 = [2, 3]$ .
- Also in Fig. 5, because the level-1 grouping pointed to by the *A*-connection of the level-2 grouping has three exit vertices, these are constrained by structural invariant 1 to map in order over to the three middle vertices of the level-2 grouping; i.e., the corresponding return tuple is [1, 2, 3].
  - The *B*-connections for the first and second middle vertices of the level-2 grouping are to the same level-1 grouping; however, the two return tuples are different, and thus are consistent with structural invariant 4.

One artifact of the greedy, left-to-right decision-tree folding method used in §4.2 and Appendix §C is that matched paths through proto-CFLOBDDs (and hence through CFLOBDDs) have a left-to-right bias in the ordering of paths with respect to Boolean-variable-to-Boolean-value assignments. This bias is captured in the following proposition.

PROPOSITION 4.1 (LEXICOGRAPHIC-ORDER PROPOSITION). Let  $ex_C$  be the sequence of exit vertices of proto-CFLOBDD C. Let  $ex_L$  be the sequence of exit vertices reached by traversing C on each possible Boolean-variable-to-Boolean-value assignment, generated in lexicographic order of assignments. Let s be the subsequence of  $ex_L$  that retains just the leftmost occurrences of members of  $ex_L$  (arranged in order as they first appear in  $ex_L$ ). Then  $ex_C = s$ .

The proof of Prop. 4.1 is provided in Appendix §B.

Earlier in this section, the "Rationale" paragraph motivated the structural invariants as enforcing an implicit "greedy left-to-right folding" of the corresponding decision tree to create the CFLOBDD, and Figure 8 illustrates the structural invariants from a syntactic/operational viewpoint. In contrast, Prop. 4.1 elucidates a semantic consequence of the structural invariants.<sup>9</sup>

To reduce clutter, our diagrams often show multiple instances of the two kinds of level-0 groupings; in fact, a CFLOBDD can contain at most one copy of each.

<sup>&</sup>lt;sup>9</sup> §4.2 gives a high-level overview of the proof that CFLOBDDs are a canonical representation of Boolean functions. In the proof of canonicity in §C, Prop. 4.1 is used in the proof of Prop. C.1, which establishes property (3) from §4.2.

Example 4.2. Prop. 4.1 can be illustrated using Fig. 5. If we use numbers to identify exit vertices,  $ex_C$  for any grouping q is the sequence [1..q.numberOfExits]. In the upper level-1 grouping in Fig. 5,  $ex_L$  is [1, 2, 2, 3], so s is [1, 2, 3]. In the level-1 grouping at the lower right,  $ex_L$  is [1, 1, 2, 2], so s is [1,2]. In the level-2 grouping, *ex*<sub>L</sub> is [1, 1, 1, 1, 2, 2, 2, 2, 2, 2, 2, 1, 1, 2, 2], so s is [1,2].

### 4.2 Canonicity of CFLOBDDs

CFLOBDDs are a canonical representation of functions over Boolean arguments, i.e., each decision tree with  $2^{2^k}$  leaves is represented by exactly one isomorphism class of level-k CFLOBDDs. (The notion of isomorphism of CFLOBDDs was introduced in footnote 8.)

THEOREM 4.3 (CANONICITY). If  $C_1$  and  $C_2$  are level-k CFLOBDDs for the same Boolean function over  $2^k$  Boolean variables, and  $C_1$  and  $C_2$  use the same variable ordering, then  $C_1$  and  $C_2$  are isomorphic.

To prove this theorem, we make use of Obs. 2.1, and argue not in terms of Boolean functions but in terms of representations of Boolean functions-specifically, we relate two kinds of Boolean-function representations

- the decision tree  $T_B$  for a Boolean function *B*, using some fixed, but otherwise unspecified, variable ordering Ord, and
- the CFLOBDD for *B*, again using variable ordering Ord.

By Obs. 2.1, we use  $T_B$  as a stand-in for B, thereby avoiding having to talk about B itself. In particular, 1000 we must establish that three properties hold:

- (1) Every level-*k* CFLOBDD represents a decision tree with  $2^{2^k}$  leaves.
- (2) Every decision tree with  $2^{2^k}$  leaves is represented by some level-k CFLOBDD.
- (3) No decision tree with  $2^{2^k}$  leaves is represented by more than one level-k CFLOBDD (up to isomorphism).
- The proof that CFLOBDDs are a canonical representation of Boolean functions is in Appendix §C. 1006 We already showed that Obligation 1 is satisfied in §3.3.4. 1007

Obligation 2 is established by showing that there is a recursive procedure for constructing a level-1008 k CFLOBDD from an arbitrary decision tree with  $2^{2^k}$  leaves (i.e., of height  $2^k$ )-see Construction 1 1009 in Appendix §C. In essence, the construction shows how such a decision tree can be folded together 1010 to form a CFLOBDD that represents the same Boolean function. The construction ensures that the 1011 structural invariants are obeyed. 1012

Obligation 3 is established by showing that (i) unfolding a CFLOBDD C into a decision tree T and 1013 then (ii) folding T back to a CFLOBDD yields a CFLOBDD that is isomorphic to C. In particular, the 1014 folding-back step applies the same algorithm we use to establish Obligation 2, namely, Construction 1015 1 from Appendix §C. Construction 1 is a *deterministic algorithm*, and thus the proof establishes that 1016 T can only be mapped to a CFLOBDD C' that is isomorphic to C. (See Prop. C.1.) 1017

Note that Obligation 1 and 2 are exactly Requirements (1) and (2) from §3.2, respectively. Moreover, 1018 Obligations 1–3 together show that Requirement (4) from §3.2 is met. 1019

#### PRAGMATICS 5 1021

The structure of the groupings in a CFLOBDD is acyclic: a level-k grouping has calls exclusively 1022 to groupings at level k-1; conversely, a given grouping at level k-1 can be called from multiple 1023 groupings, but only ones at level k. This property allows CFLOBDDs to be implemented in a 1024 functional style without side-effects. Moreover, because groupings are acyclic, storage can be 1025 managed via smart-pointer-based reference counting. 1026

The remainder of this section discusses pragmatics-namely, how some of the standard techniques 1027 for working with a functional data structure apply to CFLOBDDs. All three of the techniques 1028

discussed contribute to an implementation being able to satisfy Requirement (5) that operations ona CFLOBDD run in time polynomial in the size of the CFLOBDD.

1032

### 1033 5.1 Hash-Consing of Groupings and CFLOBDDs to Create Unique Representatives

Hash-consing [23] enforces the invariant that only a single representative exists for each value constructed from some datatype. Hash-consing should not be confused with canonicity (§4.2 and Appendix §C). Canonicity is a semantic property: if two CFLOBDDs  $C_1$  and  $C_2$  represent the same function, then  $C_1$  and  $C_2$  are isomorphic. Hash-consing concerns concrete memory representations: for a given data-structure construction pattern, only a single representative exists in memory, no matter how many times that value arises in a computation.

However, because canonicity holds for CFLOBDDs, an implementation that uses hash-consing<sup>10</sup> satisfies an even stronger form of equivalence. In particular, Thm. 4.3 can be restated to read "... then  $C_1$  and  $C_2$  are identical."

1043 Because the operations that construct Groupings and CFLOBDDs involve a certain amount of 1044 processing before the object being constructed is finally complete, we will assume that two opera-1045 tions, named RepresentativeGrouping and RepresentativeCFLOBDD, are available for explicitly 1046 maintaining the tables of representative Groupings and CFLOBDDs, respectively. For instance, a call 1047 RepresentativeGrouping(g) checks to see whether a representative for g is already in the table of 1048 representative Groupings; if there is such a representative, say h, then g is discarded and h is returned 1049 as the result; if there is no such representative, then g is installed in the table and returned as the 1050 result. The operations RepresentativeForkGrouping and RepresentativeDontCareGrouping 1051 return the unique representatives of types ForkGrouping and DontCareGrouping, respectively.

Operations discussed in §6 that create InternalGroupings, such as PairProduct (Alg. 9) and
 Reduce (Alg. 10), have the following form:

1054 Operation() { 1055 . . . 1056 InternalGrouping g = new InternalGrouping(k); 1057 // Operations to fill in the members of g, including g.AConnection and the 1058 // elements of array g.BConnections, with level-(k-1) Groupings 1059 1060 return RepresentativeGrouping(g); 1061 } 1062

The operation NoDistinctionProtoCFLOBDD (Alg. 3), which constructs the members of the familyof no-distinction proto-CFLOBDDs depicted in Fig. 7, also has this form.

1065RepresentativeCFLOBDD is similar to RepresentativeGrouping, but in addition to a Grouping1066argument, it also has a value-tuple argument. The operation ConstantCFLOBDD (Alg. 2) illustrates1067the use of RepresentativeCFLOBDD: ConstantCFLOBDD(k,v) returns a hash-consed CFLOBDD1068that represents a constant function of the form  $\lambda x_0, x_1, \ldots, x_{2^i-1}.v.$ 

In our implementation, we maintain the invariant that the Groupings that appear in the hashconsing tables are the heads of fully-fledged proto-CFLOBDDs, not mock-proto-CFLOBDDs—i.e., structural invariants (1)–(4) of Defn. 4.1 hold. When a proto-CFLOBDD p is associated with terminal values to create a CFLOBDD c, it is necessary to ensure that structural invariant (6) holds. In particular, if there are any duplicate terminal values, a "reduction" step is applied (see Alg. 10 of §6.3), which may cause smaller versions of some of the groupings in p to be constructed. The original groupings would be collected if their reference counts go to 0. However, there is

1076 1077

<sup>&</sup>lt;sup>10</sup>It can also be useful to use hash-consing for the objects of classes ReturnTuple, PairTuple, and ValueTuple.

1121

never any issue of the hash-cons tables being polluted by mock-proto-CFLOBDDs that violate theproto-CFLOBDD structural invariants.

### 1082 5.2 Equality Testing for CFLOBDDs and proto-CFLOBDDs

As discussed in §5.1, the combined effect of hash-consing and canonicity is that an implementation can maintain the invariant that, at any given time, there is a unique concrete memory representation of a given Boolean function. Consequently, it is possible to test in unit time—by comparing two pointers—whether two variables of type CFLOBDD represent the same Boolean function. This property is important in user-level applications in which various kinds of data are implemented using class CFLOBDD. For example, in applications structured as fixed-point-finding loops, this property provides a unit-cost test of whether the fixed-point has been reached.

Again, because of the use of hash-consing, it is also possible to test whether two variables of type Grouping are equal via a single pointer comparision. Because each grouping is always the highest-level grouping of some proto-CFLOBDD, the equality test on Groupings is really a test of whether two proto-CFLOBDDs are equal. The property of being able to test two proto-CFLOBDDs for equality quickly is important because proto-CFLOBDD equality tests are used during the various operations on CFLOBDDs to maintain the structural invariants from Defn. 4.1.

Finally, the ability to test two proto-CFLOBDDs for equality quickly also allows some functions typically near the beginning of the function—to identify important special-case values of parameters, which can lead to faster performance. For instance, in Alg. 1, line [10], we saw how testing whether the argument g is a NoDistinctionProtoCFLOBDD allows further recursive calls to InterpretGrouping() to be short-circuited.

### 1102 5.3 Function Caching

A function cache (or *memo function* [45]) for a function *F* is an associative-lookup table—typically a 1103 hash table—of pairs of the form [x, F(x)], keyed on the value of x. The table is consulted each time 1104 F is applied to some argument, and updated after a return value is computed for a never-before-seen 1105 argument. The technique saves the cost of re-performing the computation of F for an argument on 1106 1107 which *F* has previously been called, at the expense of performing a lookup on *F*'s argument at the beginning of each call. Our implementation of CFLOBDDs uses function caching for a number of 1108 the operations described in the remainder of the paper, such as PairProduct (Alg. 9) and Reduce 1109 (Alg. 10). To reduce clutter in the pseudo-code that we give, we elide the lines for querying and 1110 updating the cache. The full statement of such a function would have the following form: 1111

1112	F(x) {
1113	<b>if</b> cache <sub>F</sub> (x) $\neq$ NULL <b>return</b> cache <sub>F</sub> (x);
1114	
1115	$cache_F(x) = retVal;$ // Update the cache with the return value
1116	return retVal;
1117	}

Function caching involves hashing, and it is necessary to perform equality tests to resolve hash collisions. Thus, the ability to test two proto-CFLOBDDs for equality in unit time (§5.2) also improves the performance of function caching.

### 1122 6 ALGORITHMS ON CFLOBDDS

In this section and §7, we describe operations to construct or combine CFLOBDDs. To aid the reader, Tab. 1 lists the fourteen main operations on CFLOBDDs, together with references to where the algorithm for each operation is presented (and where it is discussed), along with each operation's asymptotic running time and the asymptotic running time of the analogous BDD operation. Readers

familiar with BDDs will find that the algorithms for operations on CFLOBDDs are somewhat more complicated than their BDD counterparts, mainly due to the need to maintain the CFLOBDD structural invariants (Defn. 4.1). 

6.1	Primitive CFLOBDD-Creation Operations

	Ē		Time Con	nplexity
Operation	1 ype Signature	Description	CFLOBDD	BDD
Equal (§5.2)	CFLOBDD × CFLOBDD → Boolean	Checks if two CFLOBDDs are equal	${\cal O}(1)$	<i>O</i> (1)
ConstantCFLOBDD (Alg. 2, §6.1.1)	Int $(k) \times Value (v)$ $\rightarrow CFLOBDD$	Creates a CFLOBDD for a constant function $\lambda x_0 \dots x_{2^{k-1}} . v$	O(k)	$O(2^k)$
FalseCFLOBDD (Alg. 2, §6.1.1)	$\int \operatorname{Int}(k) \longrightarrow \operatorname{CFLOBDD}$	Creates a CFLOBDD for the function $\lambda x_0 \dots x_{2^k-1} \cdot F$	O(k)	$O(2^k)$
TrueCFLOBDD (Alg. 2, §6.1.1)	$\int \operatorname{Int}(k) \rightarrow \operatorname{CFLOBDD}$	Creates a CFLOBDD for the function $\lambda x_0 \dots x_{2^{k-1}} T$	O(k)	$O(2^k)$
NoDistinctionProtoCFLOBDD (Alg. 3, §6.1.1)	$\int \operatorname{Int}(k) \\ \rightarrow \operatorname{Proto-CFLOBDD}$	Creates a NoDistinction ProtoCFLOBDD for $2^k$ variables	O(k)	N/A
ProjectionCFLOBDD (Alg. 4, §6.1.2)	$Int (k) \times Int (i) \\ \rightarrow CFLOBDD$	Creates a CFLOBDD for the function $\lambda x_0 \dots x_{2^{k-1}} . x_i$	O(k)	$O(2^k)$
FlipValueTupleCFLOBDD (Alg. 5, §6.2.1)	$CFLOBDD (c) \rightarrow CFLOBDD$	Creates a CFLOBDD such that the output values are flipped	O(1)	$O(\operatorname{size}_B(c))$
ComplementCFLOBDD (Alg. 5, §6.2.1)	$\leftarrow \text{CFLOBDD}(c)$	Creates a CFLOBDD such that the output values are complemented	${\cal O}(1)$	$O(\operatorname{size}_B(c))$
ScalarMultiplyCFLOBDD (Alg. 6, §6.2.2)	$\begin{array}{c} \text{CFLOBDD} (c) \times \text{Value} (v) \\ \rightarrow \text{CFLOBDD} \end{array}$	Creates a CFLOBDD that represents $c' = c * v$	${\cal O}(1)$	$O(\operatorname{size}_B(c))$
BinaryApplyAndReduce (Alg. 8, §6.3)	CFLOBDD $(c_1) \times$ CFLOBDD $(c_2) \times$ Operation $op \rightarrow$ CFLOBDD	Performs $c_1 \ op \ c_2$	$O(\operatorname{size}(c_1) \times \operatorname{size}(c_2))$	$O(\operatorname{size}_B(c_1) \times \operatorname{size}_B(c_2))$
PathCounting ([59, Alg. 21], §6.4.1)	$\leftarrow \text{CFLOBDD}(c)$ $\rightarrow \text{CFLOBDD}$	Computes the number of paths to every exit vertex of every grouping	O(size(c))	$O(\text{size}_B(c))$ (See [59, §10.1.2].)
Sampling ([59, Alg. 22], §6.4.2)	$\begin{array}{c} \text{CFLOBDD} (c) \\ \rightarrow \text{String} \end{array}$	Samples a path from <i>c</i>	$O(\max(vars, \operatorname{size}(c)))$	$O(\max(vars, \text{size}_B(c)))$ (See [59, $\$10.1.2$ ].)
KroneckerProduct ([59, App. G & Alg. 17], §7.2)	$\begin{array}{c} \text{CFLOBDD}\left(c_{1}\right) \times \text{CFLOBDD}\left(c_{2}\right) \\ \rightarrow \text{CFLOBDD} \end{array}$	Performs a Kronecker Product of two CFLOBDDs representing matrices	${\cal O}(1)$	$O(\operatorname{size}_B(c_1))$
MatrixMultiply ([59, Algs. 19 & 20], §7.3)	CFLOBDD × CFLOBDD → CFLOBDD	Performs matrix multiplication of two CFLOBDDs representing matrices	$O(N^3)$ , where the matrices are of size $N \times N$	$O(N^3)$
Table 1. List of operations on C of levels of the CFLOBDD). In	CFLOBDDs; size( $c$ ) denotes the size the column for the time complex	ze of CFLOBDD <i>c; vars</i> denotes the num cities of BDD operations, an occurrence	oer of Boolean variables (= of <i>c</i> refers to a BDD argum	$2^k$ , where k is the number nent of the operation, and
size $B(c)$ denotes the size of Bl	DD c. For quasi-reduced BDDs, t	the time to construct the analog of No	DistinctionProtoCFLOBDI	O is $O(2^{\kappa})$ . Note that the

complexity of MatrixMultiply is in terms of the sizes of matrices represented by  $c_1$  and  $c_2$  and not the sizes of  $c_1$  and  $c_2$ .

1226  $\lambda x_0, x_1, \ldots, x_{2^{k}-1}.v$ , where v is some constant value. ConstantCFLOBDD(k, v) uses as a subroutine 1227 NoDistinctionProtoCFLOBDD (Alg. 3), which constructs the no-distinction proto-CFLOBDD for 1228 a given level k (see also Fig. 7). ConstantCFLOBDD can be used to construct CFLOBDDs for the 1229 constant functions  $\lambda x_0, x_1, \ldots, x_{2^{k}-1}.F$  and  $\lambda x_0, x_1, \ldots, x_{2^{k}-1}.T$  (lines [6]–[10] and [11]–[15] of Alg. 2, 1230 respectively). ConstantCFLOBDD(k, v) runs in time O(k) and uses at most O(k) space.

Fig. 9. (a) CFLOBDD for  $\lambda x_0 x_1 . x_0$ ; (b) CFLOBDD for  $\lambda x_0 x_1 . x_1$ ; (c) schematic drawing of CFLOBDDs that represent projection functions of the form  $\lambda x_0, x_1, \ldots, x_{2^{k}-1} . x_i$ , when  $0 \le i < 2^{k-1}$ ; (d) schematic drawing of CFLOBDDs that represent projection functions of the form  $\lambda x_0, x_1, \ldots, x_{2^k-1} . x_i$ , when  $2^{k-1} \le i < 2^k$ .

6.1.2 Projection Functions. A second family of CFLOBDD-creation operations produces the Boolean-valued (single-variable) projection functions of the form  $\lambda x_0, x_1, \ldots, x_{2^k-1}.x_i$ , where *i* ranges from 0 to  $2^k - 1$ . Fig. 9 illustrates the structure of the CFLOBDDs that represent these functions. Alg. 4 gives pseudo-code for ProjectionCFLOBDD(*k*, *i*), which constructs the *i*<sup>th</sup> such function. ProjectionCFLOBDD(*k*, *i*) runs in time O(k) and uses at most O(k) space.

# 125312546.2 Unary Operations on CFLOBDDs

1255 This section discusses how to perform certain unary operations on CFLOBDDs:

6.2.1 FlipValueTuple Function. The function FlipValueTupleCFLOBDD applies in the special situation in which a CFLOBDD maps Boolean-variable-to-Boolean-value assignments to just two possible values; FlipValueTupleCFLOBDD flips the two values in the CFLOBDD's valueTuple field and returns the resulting CFLOBDD. In the case of Boolean-valued CFLOBDDs, this operation can be used to implement the operation ComplementCFLOBDD, which forms the Boolean complement of its argument, in an efficient manner. The pseudo-code for these functions is given in Alg. 5.
 FlipValueTupleCFLOBDD and ComplementCFLOBDD are constant-time operations.

6.2.2 Scalar Multiplication. Function ScalarMultiplyCFLOBDD of Alg. 6 applies to any CFLOBDD that maps Boolean-variable-to-Boolean-value assignments to values on which multiplication by a scalar value of type Value is defined. When Value argument v of ScalarMultiplyCFLOBDD is the special value zero, a constant-valued CFLOBDD that maps all Boolean-variable-to-Boolean-value assignments to zero is returned. ScalarMultiplyCFLOBDD runs in time proportional to the size of the argument CFLOBDD's ValueTuple.

#### 1271 6.3 Binary Operations on CFLOBDDs

This section presents an algorithm for performing binary operations on CFLOBDDs. The algorithmis parameterized in terms of a binary operation op that is to be applied pointwise to the range values

Boolean-valued– $\lor$ ,  $\land$ ,  $\oplus$ , etc. As with BDDs, such operations on CFLOBDDs can be implemented via a two-step process<sup>11</sup>

- (1) perform a product construction
- (2) perform a reduction step on the result of step one.

Just as there can be multiple occurrences of a given node in a BDD, there can be multiple occurrences of a given grouping in a CFLOBDD. To avoid a blow-up in costs, binary operations need to avoid making repeated calls on a given pair of groupings  $g_1 \in n_1$  and  $g_2 \in n_2$ . Assuming that the hashing methods used for hash-consing (§5.1) and function caching (§5.3) run in expected unit-cost time, the cost of the two-step "pair-product-followed-by-reduction" process is bounded by the product of

1368

1358

1359

1360

1361

 <sup>&</sup>lt;sup>111</sup> The two-step process is conceptual for BDDs: the two steps can be combined in an implementation (e.g., see [19, §3.3]).
 <sup>1370</sup> For CFLOBDDs, it does not appear possible to combine the two steps, at least not easily. For more details, see the Remark
 <sup>1371</sup> just after Ex. 6.1.

<sup>1372</sup> 

<sup>,</sup> Vol. 1, No. 1, Article . Publication date: December 2023.

(d) Result of applying  $\lor$  to the values in each of the terminal-value pairs [F, T] and [T, F]. At this point, it is necessary to perform a reduction that folds together the two exit vertices.

(f) Result of calling Reduce on the second Bconnection with reductionTuple [1, 1]. The two calls on Reduce produce the same B-connection proto-CFLOBDDs with identical return edges indicated by the coincidence of the blue and red dashed edges in the structure on the right. At this point, it is necessary to perform a reduction that folds together the two middle vertices.

(c) Result of calling PairProduct on (a) and (b)

(e) Result of calling Reduce on the first B-connection with reductionTuple [1, 1].

(g) After calling Reduce on the A-connection with reductionTuple [1, 1], the final result is the CFLOBDD for  $\lambda x_0, x_1.T$ .

Fig. 10. Illustration of how  $(\lambda x_0, x_1.x_0 \oplus x_1) \lor (\lambda x_0, x_1.x_0 \Leftrightarrow x_1)$  results in  $\lambda x_0, x_1.T$ .

the sizes of the two argument CFLOBDDs.<sup>12</sup> Consequently, binary operations satisfy Requirement (5); i.e., they run in (expected) time that is polynomial in the sizes of the argument CFLOBDDs.

<sup>12</sup>More precisely, let  $n \uparrow gr[i]$  denote the set of groupings at level  $i \in [0..l]$  in CFLOBDD n. The cost of  $n_1$  op  $n_2$  is bounded by  $\sum_{i=0}^{l} \sum \left\{ |g_1| \times |g_2| \mid g_1 \in n_1 \uparrow gr[i] \text{ and } g_2 \in n_2 \uparrow gr[i] \right\}$ . , Vol. 1, No. 1, Article . Publication date: December 2023.

Fig. 10 illustrates this method by showing how the CFLOBDD for  $\lambda x_0, x_1.T$  is obtained as the result of a Boolean- $\forall: (\lambda x_0, x_1.x_0 \oplus x_1) \lor (\lambda x_0, x_1.x_0 \Leftrightarrow x_1)$ . Fig. 10c shows the result of the product construction (PairProduct, Alg. 9). Figs. 10d, e, f, and g illustrate some of the steps of the reduction algorithm (Reduce, Alg. 10). Fig. 10 is discussed in more detail in Ex. 6.1.

or Grouping arguments are objects whose highest-level groupings are all at the same level.) • The operation BinaryApplyAndReduce, given as Alg. 8, starts with a call on PairProduct

(line [2]). PairProduct, given as Alg. 9, performs a recursive traversal of the two Grouping arguments, g1 and g2, to create a proto-CFLOBDD that represents a kind of cross product. PairProduct returns g, the proto-CFLOBDD formed in this way, as well as pt, a descriptor of the exit vertices of g in terms of pairs of exit vertices of the highest-level groupings of g1 and g2. (See Alg. 9, lines [2]–[5] and lines [11]–[29].)

1568

, Vol. 1, No. 1, Article . Publication date: December 2023.

Function caching (§5.3) is performed for PairProduct. Consequently, for a given invocation 1569 of BinaryApplyAndReduce on CFLOBDDs  $n_1$  and  $n_2$ , for each level l, the number of calls 1570 on PairProduct for level l is bounded by the product of the numbers of level-l groupings 1571 in  $n_1$  and  $n_2$ . Moreover, for each call on PairProduct $(q_1, q_2)$ , the number of exit vertices 1572 in grouping q is bounded by the product of the numbers of exit vertices in  $q_1$  and  $q_2$  (see 1573 line [25]). Similarly, the number of middle vertices in q is bounded by the product of the 1574 numbers of middle vertices in  $q_1$  and  $q_2$  (see line [10]). Thus, the size of g is bounded by 1575 the product of the sizes of  $q_1$  and  $q_2$ . Consequently, the cost of the call on PairProduct in 1576 line [2] of Alg. 8 is bounded by the sum over the level-number l of the products of the sizes 1577 of the level-*l* groupings in  $n_1$  and  $n_2$ —and hence polynomial in the sizes of  $n_1$  and  $n_2$ . 1578

Lines [2]–[4] of PairProduct perform special-case processing when either argument 1579 to PairProduct is a NoDistinctionProtoCFLOBDD. At level 0, these checks-along with 1580 line [5]—implement the base case of PairProduct. However, at levels greater than 0, they 1581 allow PairProduct to return immediately, without making any recursive calls to traverse  $q_1$ 1582 or  $q_2$ , potentially saving considerable work. 1583

 BinaryApplyAndReduce then uses pt, together with op and the value tuples from CFLOBDDs 1584 n1 and n2, to create the tuple deducedValueTuple of leaf values that should be associated 1585 with the exit vertices (see Alg. 8, line [3]]). 1586

However, deducedValueTuple is a *tentative* value tuple for the constructed CFLOBDD; because of Structural Invariant 6, this tuple needs to be collapsed if it contains duplicate 1588 values. 1589

- BinaryApplyAndReduce obtains two tuples, inducedValueTuple and 1590 inducedReductionTuple, which describe the collapsing of duplicate leaf values, by 1591 calling the subroutine CollapseClassesLeftmost (Alg. 7): 1592
- Tuple inducedValueTuple serves as the final value tuple for the CFLOBDD constructed 1593 by BinaryApplyAndReduce. In inducedValueTuple, the leftmost occurrence of a value 1594 in deducedValueTuple is retained as the representative for that equivalence class of 1595 values. For example, if deducedValueTuple is [2, 2, 1, 1, 4, 1, 1], then inducedValueTuple 1596 is [2, 1, 4]. 1597

The use of leftward folding is dictated by Structural Invariant 2b.

 Tuple inducedReductionTuple describes the collapsing of duplicate values that took place in creating inducedValueTuple from deducedValueTuple: inducedReductionTuple is the same length as deducedValueTuple, but each entry inducedReductionTuple(i) gives the ordinal position of deducedValueTuple(i) in inducedValueTuple. For example, if deducedValueTuple is [2, 2, 1, 1, 4, 1, 1] (and thus inducedValueTuple is [2, 1, 4]), then inducedReductionTuple is [1, 1, 2, 2, 3, 2, 2]-meaning that positions 1 and 2 in deducedValueTuple were folded to position 1 in inducedValueTuple, positions 3, 4, 6, and 7 were folded to position 2 in inducedValueTuple, and position 5 was folded to position 3 in inducedValueTuple.

(See Alg. 8, line [4], as well as Alg. 7.)

• Finally, BinaryApplyAndReduce performs a corresponding reduction on Grouping g, by 1609 calling the subroutine Reduce, which creates a new Grouping in which g's exit vertices are 1610 folded together with respect to tuple inducedReductionTuple (Alg. 8, line [5]). 1611

Procedure Reduce, given as Alg. 10, recursively traverses Grouping g, working in the 1612 backwards direction, first processing each of g's B-connections in turn, and then processing 1613 g's A-connection. In both cases, the processing is similar to the (leftward) collapsing of 1614 duplicate leaf values that is carried out by BinaryApplyAndReduce: 1615

1604

1605

1606

1607

- In the case of each *B*-connection, rather than collapsing with respect to a tuple of duplicate final values, Reduce's actions are controlled by its second argument, reductionTuple, which clients of Reduce-namely, BinaryApplyAndReduce and Reduce itself-use to inform Reduce how g's exit vertices are to be folded together. For instance, the value of reductionTuple could be [1, 1, 2, 2, 3, 2, 2]—meaning that exit vertices 1 and 2 are to be folded together to form exit vertex 1, exit vertices 3, 4, 6, and 7 are to be folded together to form exit vertex 2, and exit vertex 5 by itself is to form exit vertex 3.

In Alg. 10, line [12], the value of reductionTuple is used to create a tuple that indicates the equivalence classes of targets of return edges for the *B*-connection under consideration (in terms of the new exit vertices in the Grouping that will be created to replace g).

Then, by calling the subroutine CollapseClassesLeftmost, Reduce obtains two tuples, inducedReturnTuple and inducedReductionTuple, that describe the collapsing that needs to be carried out on the exit vertices of the *B*-connection under consideration (Alg. 10, line [13]).

Tuple inducedReductionTuple is used to make a recursive call on Reduce to process the *B*-connection; inducedReturnTuple is used as the return tuple for the Grouping returned from that call. Note how the call on InsertBConnection (Alg. 11) in line [15] of Reduce enforces Structural Invariant 4.

- As the *B*-connections are processed, Reduce uses the position information returned from InsertBConnection to build up the tuple reductionTupleA (Alg. 10, line [16]). This tuple indicates how to reduce the A-connection of g.
- Finally, via processing similar to what was done for each *B*-connection, two tuples are 1639 obtained that describe the collapsing that needs to be carried out on the exit vertices of the 1640 A-connection, and an additional call on Reduce is carried out. (See Alg. 10, lines [18]-[21].) 1641

1642 Function caching (§5.3) is performed for Reduce, with respect to both arguments g and 1643 reductionTuple. Consequently, for a given invocation of BinaryApplyAndReduce on CFLOBDDs 1644  $n_1$  and  $n_2$ , the number of calls to Reduce is proportional to the size of the proto-CFLOBDD g returned 1645 by the call on PairProduct in line [2] of Alg. 8, which-as argued above-is polynomial in the sizes 1646 of  $n_1$  and  $n_2$ . The amount of work performed directly by Reduce itself is polynomial in the size of 1647 its arguments g and reductionTuple. Consequently, the total cost of BinaryApplyAndReduce is 1648 polynomial in the sizes of  $n_1$  and  $n_2$ .

1649 Recall that a call on RepresentativeGrouping(g) may have the side effect of installing g into 1650 the table of memoized Groupings. We do not wish for this table to ever be polluted by non-well-1651 formed proto-CFLOBDDs. Thus, there is a subtle point as to why the grouping g constructed 1652 during a call on PairProduct meets Structural Invariant 4-and hence why it is permissible to call 1653 RepresentativeGrouping(g) in line [29] of Alg. 9. The proof can be found in [59, Appendix D].

1654 Lastly, in the case of Boolean-valued CFLOBDDs, there are 16 possible binary operations, corre-1655 sponding to the 16 possible two-argument truth tables  $(2 \times 2 \text{ matrices with Boolean entries})$ . All 16 1656 binary operations are special cases of BinaryApplyAndReduce; these can be performed by passing 1657 BinaryApplyAndReduce an appropriate value for argument op (i.e., some  $2 \times 2$  Boolean matrix). 1658

*Example 6.1.* Fig. 10 illustrates how the CFLOBDD for  $\lambda x_0, x_1.T$  is created from the "or" ( $\vee$ ) of 1659 the CFLOBDDs for  $\lambda x_0, x_1, x_0 \oplus x_1$  and  $\lambda x_0, x_1, x_0 \Leftrightarrow x_1$ . Fig. 10c is the result of calling PairProduct 1660 on the CFLOBDDs for  $\lambda x_0, x_1.x_0 \oplus x_1$  and  $\lambda x_0, x_1.x_0 \Leftrightarrow x_1$ . After  $\vee$  is applied to the values in 1661 each of the terminal-value pairs [F, T] and [T, F], we obtain a mock-CFLOBDD that has two 1662 exit vertices associated with terminal value T. To restore the structural invariants and create a 1663 CFLOBDD, the two exit vertices must be folded together, and a reduction performed on each of 1664 the two B-connections. In each case, Reduce is called with reductionTuple [1, 1]. Because these 1665

reductions result in the same B-connection proto-CFLOBDDs with identical return edges (Fig. 10e 1667 and Fig. 10f), which would be discovered by InsertBConnection (Alg. 11), it is necessary to fold 1668 1669 together the two middle vertices and perform a reduction on the A-connection: Reduce is called with reductionTuple [1, 1], This step produces the CFLOBDD for  $\lambda x_0, x_1.T$  (Fig. 10g). 1670

Remark. For BDDs, the two-step process of "pair-product-followed-by-reduction" need only be conceptual. Binary operations on BDDs can be implemented during a single recursive pass by performing the appropriate value-reduction operation on terminal values, and then, as the recursion unwinds, having the BDD-node constructor perform hash-consing (suppressing the construction of don't-care nodes) so that non-reduced structures are never created [19, §3.3].

1676 Such an approach does not seem to be possible with CFLOBDDs because reduction is not obtained 1677 as a side-effect of hash-consing. The flow of control in Reduce (Alg. 10) follows the sequence of 1678 elements of a matched path backwards. Reduce makes recursive calls for the B-connection proto-1679 CFLOBDDs and then a recursive call for the A-connection proto-CFLOBDD (rather than working 1680 bottom-up from level-0 groupings to level-k groupings, which would be the analogue of the bottom-1681 up construction performed with BDDs.) Consequently, our CFLOBDD implementation maintains 1682 the weaker invariant that the Groupings that appear in the hash-consing tables are the heads of 1683 fully-fledged proto-CFLOBDDs, not mock-proto-CFLOBDDs-i.e., structural invariants (1)-(4) of 1684 Defn. 4.1 hold. While such Groupings may have to be reduced later, there is never any issue of 1685 the hash-cons tables being polluted by mock-proto-CFLOBDDs that violate the proto-CFLOBDD 1686 structural invariants.

Some unary operations on CFLOBDDs may also need to apply Reduce. For example, if the terminal values of a CFLOBDD are numeric values, the unary function that squares all terminal values could initially result in a mock-CFLOBDD that has duplicate terminal values. Reduce, with an appropriate ReductionTuple, would be then applied to create the corresponding CFLOBDD.

In a manner similar to the binary operations on CFLOBDDs, we can perform ternary operations on CFLOBDDs. Details about how to perform ternary operations can be found in [59, Appendix E.1]. Other operations, such as restriction  $(f|_{x_i=v})$  and existential quantification  $(\exists x_i, f)$  can also be performed on a CFLOBDD; the corresponding algorithms can be found in Appendices E.2 and E.3, respectively, of [59].

#### 6.4 Path Counting and Sampling

A CFLOBDD whose terminal values are non-negative numbers can be used to represent a discrete distribution over the set of assignments to the Boolean variables. An assignment-or equivalently, the corresponding matched path in the CFLOBDD-is considered to be an elementary event. The "weight" of the elementary event is the terminal value. The probability of a matched path p is the weight of p divided by the total weight of the CFLOBDD—the sum of the weights obtained by following each of the CFLOBDD's matched paths. Fortunately, it is possible to compute the aforementioned denominator by computing, for each of the terminal values, the number of matched paths that lead to that terminal value (§6.4.1). With those numbers in hand, it is then possible to sample an assignment/path according to the distribution that the CFLOBDD represents (§6.4.2).

1707 The same approach can be used for CFLOBDDs whose terminal values are complex numbers, 1708 except that the weight of a matched path is the square of the terminal value's absolute value. This 1709 approach is used in the application of CFLOBDDs to quantum simulation (§9 and §10.2.2). 1710

6.4.1 Path Counting. Recall that every terminal value is connected to one exit vertex of the 1711 top-level grouping of the CFLOBDD. Every exit vertex of a grouping is, in turn, connected to 1712 exit vertices of internal groupings. Therefore, to compute the number of matched paths for every 1713 terminal value, we need to compute the path-counts from the entry vertex of a grouping to every 1714 1715

exit vertex of that grouping, for every grouping in the CFLOBDD. For each grouping g, we would like to compute a vector of path-counts, in which the  $i^{th}$  element is the number of matched paths from g's entry vertex to the  $i^{th}$  exit vertex of g. To compute this information, we can break it down into (i) computing the number of matched paths from g's entry vertex to g's middle vertices; (ii) computing the number of matched paths from g's middle vertices to g's exit vertices; and (iii) combining this information to obtain the number of matched paths from g's entry vertex to g's exit vertices.

1723 Consider a Grouping q at level l with e exit vertices. Suppose that q.AConnection has p exit vertices, *q.BConnections*[*j*] has  $k_i$  exit vertices, and let *q.BReturnTuples*[*j*] be the return edges 1724 from *q.BConnections*[*j*]'s exit vertices to *q*'s exit vertices. For step (i), we recursively compute the 1725 path-counts for *q*. A Connection, which yields a vector of path-counts  $v_A$  of size  $1 \times p$ . Step (ii) creates 1726 a matrix  $M_B$  of size  $p \times e$ , in which the  $j^{th}$  row is the vector of path-counts from the  $j^{th}$  middle 1727 vertex of q to q's exit vertices. Step (iii) is the vector-matrix multiplication  $v_A \times M_B$ , which yields 1728 g's path-count vector, of size  $1 \times e$ . The base-case path-count vectors are [1, 1] for a ForkGrouping 1729 and [2] for a *DontCareGrouping*. 1730

Because the exit vertices of g.BConnections[j] are connected to g's exit vertices via g.BReturnTuples[j], the  $j^{th}$  row of  $M_B$  is the product of the path-count vector for g.BConnections[j](of size  $1 \times k_j$ ) and a "permutation matrix"  $PM^{g.BReturnTuples[j]}$  (of size  $k_j \times e$ ). Each entry of PM is either 0 or 1; each row must have exactly one 1; and each column must have at most one 1.

This definition can be stated equationally, where the expression in large brackets represents  $M_B$ .

 $numPathsToExit_{1\times e}^{g} =$ 1738  $[1,1]_{1\times 2}$ if g = ForkGrouping 1739  $\begin{cases} [2]_{1\times 1} \\ numPathsToExit_{1\times p}^{g.AConnection} \times \\ \\ numPathsToExit_{1\times k_j}^{g.BConnections[j]} \times PM_{k_j\times e}^{g.BReturnTuples[j]} \\ \\ \vdots \end{cases} \end{cases}$ 1740 if g = DontCareGrouping 1741 1742 1743 1744 otherwise 1745 1746 1747

*Example 6.2.* For the five proto-CFLOBDDs depicted in Fig. 11, the vectors of path-counts are computed as follows (read top-to-bottom by level):

level 2	level 1	level 0
$\begin{bmatrix} 9 & 7 \end{bmatrix} = \begin{bmatrix} 3 & 1 \end{bmatrix} \times \begin{bmatrix} 3 & 1 \\ 0 & 4 \end{bmatrix}$	$\begin{bmatrix} 3 & 1 \end{bmatrix} = \begin{bmatrix} 1 & 1 \end{bmatrix} \times \begin{bmatrix} 2 & 0 \\ 1 & 1 \end{bmatrix}$ $\begin{bmatrix} 4 \end{bmatrix} = \begin{bmatrix} 2 \end{bmatrix} \times \begin{bmatrix} 2 \end{bmatrix}$	$\begin{bmatrix} 1 & 1 \end{bmatrix}$ [2]

Pseudo-code for the path-counting algorithm can be found as [59, Alg. 21].

6.4.2 Sampling an Assignment. Our goal is to sample a matched path from the distribution of matched paths of a given CFLOBDD, and return the corresponding assignment. As in §3.3.4, we assume that an assignment is an array of Booleans, whose entries—starting at index-position 1—are the values of successive variables. Suppose that the CFLOBDD has *l* levels. If the distribution were given as a vector of weights,  $W = [w_1...w_{2^2}l]$ , as one would have in the corresponding decision tree,

1813

the probability of selecting the  $p^{th}$  matched path is given by

$$Prob(p) = \frac{w_p}{\sum_{i=1}^{2^{2^l}} w_i}.$$
(5)

<sup>1769</sup> In a CFLOBDD that represents a distribution, we do not have access to *W* directly. Suppose that <sup>1770</sup>  $W' = [w'_1, \dots, w'_K]$  is the vector of terminal values of the CFLOBDD. The *K* values of *W'* are exactly <sup>1771</sup> the *K* different values that appear in *W*; however, many matched paths that start at the top-level <sup>1772</sup> entry vertex lead to the same terminal value, say  $w'_m$ . Fortunately, the path-counting method from <sup>1773</sup> §6.4.1 provides us with part of what is needed via *NumPathsToExit* of the top-level grouping.

$$\sum_{i=1}^{2^{2^{l}}} w_{i} = \sum_{j=1}^{K} w_{j}' \times numPathsToExit[j]$$

Thus, while Eqn. (5) becomes  $Prob(p) = \frac{w_p}{\sum_{j=1}^{K} w'_j \times numPathsToExit[j]}$  this observation gives us

no guidance about how to select a matched path p with that probability.

Rather than selecting a single matched path immediately, what we can do instead is to select the entire set of matched paths that reach a given terminal value. This selection can be done by sampling from the exit vertices of the top-level grouping according to the probability distribution

$$Prob'(\text{Path ends at terminal value } w'_t) = \frac{w'_t \times numPathsToExit[t]}{\sum_{j=1}^{K} w'_j \times numPathsToExit[j]}$$
(6)

The result of this sampling step is the index of an exit vertex of the top-level grouping, which will be used for further sampling among the (indirectly) "retrieved" set of matched paths. What remains to be done is to uniformly sample a matched path from that set, and return the assignment that corresponds to that matched path.

To achieve this goal, we take advantage of the structure of matched paths to break the assignment/path-sampling problem down to a sequence of smaller assignment/path-sampling problems that can be performed recursively. At each grouping g visited by the algorithm, the goal is to uniformly sample a matched path from the set of matched paths  $P_{g,i}$  (in the proto-CFLOBDD headed by g) that lead from g's entry vertex to a specific exit vertex i of g.

Consider a grouping *q* and a given exit vertex *i*. For each middle vertex *m* of *q*, there is some 1797 number of matched paths—possibly 0—from the entry vertex of q that pass through m and eventually 1798 reach exit vertex *i*. Those numbers of matched paths, when divided by  $|P_{q,i}|$ , represent a distribution 1799  $D_i$  on the set of g's middle vertices. Consequently, the first step toward uniformly sampling a 1800 matched path from the set  $P_{q,i}$  is to sample the index of a middle vertex of *g* according to distribution 1801  $D_i$ . Call the result of that sampling step  $m_{index}$ . Thus, to sample a matched path from the entry vertex 1802 of q to exit vertex i, we (i) sample a middle vertex of q according to  $D_i$  to obtain  $m_{index}$ ; (ii) uniformly 1803 sample a matched path from g.AConnection with respect to the exit vertex of g.AConnection that 1804 returns to  $m_{index}$ ; (iii) uniformly sample a matched path from g.BConnections[ $m_{index}$ ] with respect 1805 to whichever of its exit vertices is connected to the  $i^{th}$  exit vertex of g; and (iv) concatenate the 1806 assignments obtained from steps (ii) and (iii). 1807

<sup>1808</sup> Only the B-connections of *g* whose exit vertices are connected to *i* (the distinguished exit vertex of <sup>1809</sup> *g*) can contribute to the paths leading to *i*, and hence we need to select a middle vertex from among <sup>1810</sup> those for which the B-connection grouping can lead to *i*. For such an *i*-connected B-connection <sup>1811</sup> grouping *k*, let  $(g.BReturnTuples[k])^{-1}[i]$  denote the exit vertex of g.BConnections[k] that leads to <sup>1812</sup> *i*; i.e.,  $\langle j, i \rangle \in g.BReturnTuples[k] \Leftrightarrow (g.BReturnTuples[k])^{-1}[i] = j$ .

The path-counts for the number of matched paths of *q*'s B-connections (available via the vector NumPathsToExit for each of g's B-connections, denoted by, e.g., numPathsToExit<sup>g.BConnections[k]</sup>) only considers matched paths from q's middle vertices to q's exit vertices. However, to sample  $m_{index}$  correctly, we need to consider all of the matched paths from q's entry vertex to q's exit vertex i. Hence, we multiply the number of matched paths from *q*'s entry vertex to a middle vertex of *q* (of interest to us because it is connected to a B-connection that is connected to *i*), denoted by, e.g., *numPathsToExit<sup>g.AConnection</sup>*[k], to the number of matched paths from that same middle vertex to q's exit vertex i. Thus, the probability associated with a given  $m_{index}$  is as follows (where q.A denotes q.AConnection, *q*.*B*[*k*] denotes *q*.*BConnections*[*k*], and *q*.*BRT* denotes *q*.*BReturnTuples*):

$$\frac{numPathsToExit^{g.A}[m_{index}] \times numPathsToExit^{g.B}[m_{index}][(g.BRT[m_{index}])^{-1}[i]]}{g.numPathsToExit[i]}$$
FLOBDD for
(7)

 $\lambda w, x, y, z.(w \wedge x) \lor (y \wedge z),$ with variable ordering  $\langle w, x, y, z \rangle$ .

Example 6.3. Consider the CFLOBDD depicted in Fig. 11, and suppose that the goal is to sample a matched path that leads to terminal value T. From Ex. 6.2, we know that (i) the outermost grouping has 7 matched paths that lead to T, and (ii) NumPathsToExit is [3, 1] and [4] for the

upper and lower level-1 groupings, respectively. Both of the outermost grouping's middle vertices 1834 have return edges that lead to T; thus, from Eqn. (7), we should sample the middle vertices with 1835 probabilities 1836

$$Prob(m_{index} = 1) = \frac{[3,1][1] \times [3,1][2]}{7} = \frac{3 \times 1}{7} = \frac{3}{7} \qquad Prob(m_{index} = 2) = \frac{[3,1][2] \times [4][1]}{7} = \frac{1 \times 4}{7} = \frac{4}{7}$$

Once  $m_{index}$  has been selected in accordance with Eqn. (7), we recursively sample a matched 1839 path-and its assignment  $a_A$ -from *q*.*AConnection* with respect to exit vertex  $m_{index}$  (step (ii)). We 1840 also recursively sample a matched path—and its assignment  $a_B$ —from  $q.BConnection[m_{index}]$  with 1841 respect to the exit vertex  $(q.BReturnTuples[m_{index}])^{-1}[i]$  that leads to q's exit vertex i (step (iii)). 1842 Step (iv) produces the assignment  $a = a_A || a_B$ . 1843

As for the base cases of the recursion, for a DontCareGrouping, we randomly choose one of the 1844 paths 0 or 1 with probability 0.5, returning the assignment "0" or "1" accordingly; for a ForkGrouping, 1845 the designated exit vertex—either 1 or 2—specifies a unique assignment: "0" or "1," respectively. 1846 1847

Pseudo-code for the assignment-sampling algorithm can be found as [59, Alg. 22].

For a CFLOBDD at level l, the sampling operation involves constructing an assignment of size  $2^{l}$ . 1848 Hence, the cost of sampling is at least as large as the size of the sampled assignment. However, the 1849 size of the argument CFLOBDD also influences the cost of sampling; although not every grouping 1850 of the CFLOBDD is necessarily visited when sampling an assignment, we can say that the cost of 1851 the sampling operation is bounded by  $O(\max(2^l, \text{size of argument CFLOBDD}))$ . 1852

#### **CFLOBDD ALGORITHMS FOR MATRICES AND VECTORS** 7 1854

In this section, we discuss how to represent matrices and vectors using CFLOBDDs, and how to 1855 perform some important operations on them. 1856

#### **Representing Matrices and Vectors using CFLOBDDs** 7.1 1858

Matrix Representation. We represent square matrices using CFLOBDDs by having the Boolean 1859 variables correspond to bit positions in the row and column indices. That is, suppose that M is a 1860  $2^n \times 2^n$  matrix; M is represented using a CFLOBDD over 2n Boolean variables  $\{x_0, x_1, \ldots, x_{n-1}\} \cup$ 1861

1857

Fig. 12. Why a  $\sqrt{P} \times \sqrt{P}$ -decomposition is the natural problem decomposition for divide-and-conquer algorithms on structures represented as CFLOBDDs.

1884 { $y_0, y_1, \ldots, y_{n-1}$ }, where the variables { $x_0, x_1, \ldots, x_{n-1}$ } represent the successive bits of x—the first 1885 index into M—and the variables { $y_0, y_1, \ldots, y_{n-1}$ } represent the successive bits of y—the second 1886 index into M, with log n + 1 levels.<sup>13</sup> The indices of elements of matrices represented in this way 1887 start at 0; for example, the upper-left corner element of a matrix M is M(0, 0). When n = 2, M(0, 0)1888 corresponds to the value associated with the assignment [ $x_0 \mapsto 0, x_1 \mapsto 0, y_0 \mapsto 0, y_1 \mapsto 0$ ].

It is often convenient to use either the *interleaved* ordering—i.e., the order of the Boolean variables is chosen to be  $x_0, y_0, x_1, y_1, \ldots, x_{n-1}, y_{n-1}$ —or the *reverse-interleaved* ordering—i.e., the order is  $y_{n-1}, x_{n-1}, y_{n-2}, y_{n-2}, \ldots, y_0, x_0$ . One nice property of the interleaved-variable ordering is that, as we work through each pair of variables in an assignment, the matrix elements that remain "in play" represent a sub-block of the full matrix.

There is an important, non-standard consequence of using a CFLOBDD to represent a matrix that 1894 very likely is not apparent from the discussion above, having to do with the sizes of subproblems 1895 in a divide-and-conquer algorithm. In fact, the same issue arises in designing a divide-and-conquer 1896 algorithm over any data structure represented via a CFLOBDD, as illustrated in Fig. 12. Suppose 1897 that a CFLOBDD C represents a decision tree  $T_C$  that has  $\log_2 P$  variables, and thus P leaves. The 1898 A-connection proto-CFLOBDD accounts for half the variables, namely,  $\frac{\log_2 P}{2}$ , and the B-connection 1899 proto-CFLOBDDs account for the remaining half. The natural way to divide C in a divide-and-1900 conquer algorithm is at the middle vertices of the outermost grouping: process the A-connection 1901 proto-CFLOBDD, and then the B-connection proto-CFLOBDDs (or vice versa). In  $T_C$ , this division 1902 corresponds to the tree partitioning shown in the lower-right corner of Fig. 12: C's A-connection 1903 proto-CFLOBDD corresponds to the red tree rooted at the apex of  $T_C$  (which has  $\sqrt{P}$  leaves); C's 1904 B-connection proto-CFLOBDDs correspond to the  $\sqrt{P}$  green trees in the bottom half of  $T_C$  (each 1905 1906 of which has  $\sqrt{P}$  leaves). In contrast with standard divide-and-conquer algorithms, which often 1907 divide a problem into two subproblems of half size, this approach divides the original problem into

1911

1908

1880

 <sup>&</sup>lt;sup>13</sup>Matrices of other sizes, including non-square matrices, can be represented by embedding them within a larger square
 matrix. For matrices with > 2 dimensions, there would be a set of Boolean variables for the index-bits of each dimension.

 $\sqrt{P}$  + 1 subproblems, each of size  $O(\sqrt{P})$ . With CFLOBDDs, in contrast to decision trees, there is the potential for subproblems to be shared among the A-connection and B-connections, so one ends up with some number of subproblems  $\gamma$  (= 1 + the number of middle vertices), each of size  $O(\sqrt{P})$ .

Whereas with a decision tree it would be easy to take the conventional approach of dividing a problem into two problems of half *size*—using the left child and right child of the apex, in essence "peeling off" the topmost ply, such a division is not convenient for CFLOBDDs because the decision variable for the topmost ply is associated with the level-0 grouping found by following the A-connection of the A-connection of the . . ., etc. For CFLOBDDs, the natural structure of a divideand-conquer algorithm lies with the A-connection proto-CFLOBDD and the set of B-connection proto-CFLOBDDs—a division based on dividing *the number of variables* in half.

<sup>1922</sup> In certain cases, including matrix multiplication (§7.3), the  $\gamma \times \sqrt{P}$ -decomposition structure forced <sup>1923</sup> us to rethink how to perform various algorithms.

Let us now consider how such a decomposition works for an  $N \times N$  matrix M, assuming the interleaved-variable ordering, where  $N = 2^n$ . Thus, n is the number of bits in a row-index (respectively, column-index); there are 2n Boolean variables in total; and  $P = N^2$ . M would be decomposed into  $\sqrt{P} = \sqrt{N^2} = N$  sub-matrices, each of size  $\sqrt{N} \times \sqrt{N}$ . At top level, the A-connection of the CFLOBDD for M captures commonalities in the  $\sqrt{N} \times \sqrt{N}$  block structure of M, and the B-connections represent the blocks: sub-matrices of M of size  $\sqrt{N} \times \sqrt{N}$ .

For instance, when a level-3 CFLOBDD is used to represent a matrix, there are  $2n = 8 = 2^3$ 1931 index variables—i.e., n = 4 variables for each dimension—so the matrix is of size  $16 \times 16$ . Its natural 1932 constituents are level-2 proto-CFLOBDDs, which each have  $2^2 = 4$  index variables. Thus, there are 2 1933 A-connection variables for each dimension of the block structure, and 2 B-connection variables for 1934 each dimension of the sub-matrix for a block. Consequently, a matrix of size  $16 \times 16$  is decomposed 1935 into 16 (=  $4 \times 4 = \sqrt{16} \times \sqrt{16}$ ) blocks, each of size  $4 \times 4 = \sqrt{16} \times \sqrt{16}$ . With level-4 CFLOBDDs, 1936 one has n = 8 variables for each dimension in the full-size matrix. Thus, there are 4 A-connection 1937 variables for each dimension of the block structure, and 4 B-connection variables for each dimension 1938 of the sub-matrix for a block. Consequently, a matrix of size  $256 \times 256$  is decomposed into 256 1939  $(= 16 \times 16 = \sqrt{256} \times \sqrt{256})$  blocks, each of size  $16 \times 16 = \sqrt{256} \times \sqrt{256}$ . 1940

In general, an  $N \times N$  matrix is decomposed according to its  $\sqrt{N} \times \sqrt{N}$  block structure, where each block is of size  $\sqrt{N} \times \sqrt{N}$ . With CFLOBDDs, one hopes that many of the blocks are shared among the B-connections (and possibly some blocks are even structurally similar to the block structure itself, represented by the A-connection), so that one ends up with some—hopefully small—number of subproblems  $\gamma$ , each of size  $\sqrt{N} \times \sqrt{N}$ .

The CFLOBDD decomposition discussed above is different from (i) the natural decomposition of a matrix represented via a BDD, and (ii) the decomposition used in most divide-and-conquer algorithms on matrices. Both (i) and (ii) use  $\frac{n}{2} \times \frac{n}{2}$ -decompositions (and thus decompose a matrix of size 16 × 16 into 4 sub-matrices, each of size 8 × 8, and decompose a matrix of size 256 × 256 into 4 sub-matrices, each of size 128 × 128).

*Vector Representation.* A vector can be represented via a CFLOBDD in a manner that is similar to, but simpler, than the way matrices are represented. A vector of size  $2^n \times 1$  can be represented by a CFLOBDD whose highest level is log *n*. Suppose that *V* is a  $2^n \times 1$  vector; a CFLOBDD representing *V* would have *n* Boolean variables  $\{x_0, x_1, \ldots, x_{n-1}\}$  with the variables  $\{x_0, x_1, \ldots, x_{n-1}\}$  representing the successive bits of *x*—the index into *V*. We typically use either the increasing variable ordering or decreasing variable ordering to represent vectors. (Similar to matrices, vectors of other sizes can be embedded within a larger vector of the form  $2^n \times 1$ .)

# 1961 7.2 Kronecker Product

When using CFLOBDDs to represent matrices on which Kronecker products are performed, we
 typically use the interleaved-variable ordering. Below, we describe two variants of Kronecker
 product that result in different interleavings of the index variables of the argument matrices.

<sup>1965</sup> *Variant 1.* Suppose that matrices *W* and *V* are represented by level-*k* CFLOBDDs with value <sup>1966</sup> tuples  $[w_0, \ldots, w_m]$  and  $[v_0, \ldots, v_n]$ , respectively. To create the CFLOBDD for  $W \otimes V$ ,

- (1) Create a level k + 1 grouping that has m + 1 middle vertices, corresponding to the values  $[w_0, \ldots, w_m]$ , and (m + 1)(n + 1) exit vertices, corresponding to the terminal values  $[w_i v_j : i \in [0..m], j \in [0..n]]$ , where the terminal values are ordered lexicographically by their (i, j) indexes; i.e.,  $w_0v_0, w_0, v_1, \ldots, w_mv_{n-1}, w_m, v_n$ . The grouping's *A*-connection is the proto-CFLOBDD of *W*, with return edges that map the *i*<sup>th</sup> exit vertex to middle vertex  $w_i$ .
  - (2) For each middle vertex, which corresponds to some value  $w_i$ ,  $0 \le i \le m$ , create a *B*-connection to the proto-CFLOBDD of *V*, with return edges that map the  $j^{th}$  exit vertex to the exit vertex of the level k + 1 grouping that corresponds to the value  $w_i v_i$ .
    - (3) If any of the values in the sequence  $[w_i v_j : i \in [0..m], j \in [0..n]]$  are duplicates, make an appropriate call on Reduce to fold together the classes of exit vertices that are associated with the same value, thereby creating a canonical multi-terminal CFLOBDD.

<sup>1979</sup> The construction through step (2) is illustrated in Fig. 13.

Pseudo-code for the algorithm can be found in [59, App.G].

With this algorithm, if  $x \bowtie y$  represents the variable ordering of W and  $w \bowtie z$  represents the variable ordering of V (where  $\bowtie$  denotes the operation to interleave two variable orderings), then  $W \otimes V$  has the variable ordering  $(x||w) \bowtie (y||z)$  (where || denotes the concatenation of two sequences of variables).

Variant 2. There is a second way to perform a Kronecker product of W and V, which results in a representation of  $W \otimes V$  that has the variable ordering  $(x \bowtie w) \bowtie (y \bowtie z)$ . Pseudo-code for that algorithm can be found as [59, Alg. 17].

# 7.3 Matrix Multiplication

Fig. 13. Level-*k* CFLOBDDs for matrices *W* and *V*, and the level-(k + 1) CFLOBDD for  $W \otimes V$ .

The multiplication algorithm for CFLOBDDs presented here is similar to the standard  $O(N^3)$  algorithm for multiplying two  $N \times N$  matrices. There is a potential for savings because each of the argument CFLOBDDs may have a large number of shared substructures, and function caching can be used to detect when a sub-problem has already been performed, in which case the proto-CFLOBDD for the answer can be returned immediately.

Our starting point is the observation that when the interleaved-variable ordering is used, at top level the A-connection of a CFLOBDD-represented matrix M captures commonalities in the  $\sqrt{N} \times \sqrt{N}$  block structure of M, and the B-connections represent sub-matrices of M of size  $\sqrt{N} \times \sqrt{N}$ . By analogy with other kinds of multi-terminal CFLOBDDs, at top-level one can think of the A-connection as a multi-terminal CFLOBDD whose value tuple is the sequence of B-connections—roughly, the A-connection is a  $\sqrt{N} \times \sqrt{N}$  matrix with  $\sqrt{N} \times \sqrt{N}$ -matrix-valued leaves.

Suppose that *P* and *Q* are two  $N \times N$  matrices represented by CFLOBDDs  $C_P$  and  $C_Q$ , respectively. The respective top-level A-connections,  $A_P$  and  $A_Q$ , are matrices of size  $\sqrt{N} \times \sqrt{N}$  with matrixvalued cells of size  $\sqrt{N} \times \sqrt{N}$ . To multiply *P* and *Q*, we first recursively multiply  $A_P$  and  $A_Q$ . This 2020

operation defines which cells of  $A_P$  and  $A_Q$  get multiplied and added—and the answer is returned as a collection of symbolic expressions (of a form that will be described shortly). Using this information, we recursively call matrix multiplication and matrix addition on the B-connections, as appropriate. For the base case of the recursion—namely, level 1, which represents matrices of size  $2 \times 2$ —we can enumerate all the individual cases of possible matrix structures (i.e., the patterns of which cells hold equal values), and build the CFLOBDDs that result from a matrix multiplication in each case.

We now describe how the symbolic information mentioned above is organized, and how operations of addition and multiplication are performed on the data type in which the symbolic information is represented. The challenge that we face is that at all levels below top-level, we do not have access to a *value* for any cell in a matrix. However, we can use the exit vertices as variables.

*Example 7.1.* Suppose that we are multiplying two level-1 groupings that, when considered as  $2 \times 2$  matrices over their respective exit vertices  $[ev_1, ev_2]$  and  $[ev'_1, ev'_2, ev'_3]$ , have the forms shown on the left

$$\begin{bmatrix} ev_1 & ev_1 \\ ev_2 & ev_2 \end{bmatrix} \times \begin{bmatrix} ev_1' & ev_2' \\ ev_1' & ev_3' \end{bmatrix} = \begin{bmatrix} ev_1ev_1' + ev_1ev_1' & ev_1ev_2' + ev_1ev_3' \\ ev_2ev_1' + ev_2ev_1' & ev_2ev_2' + ev_2ev_3' \end{bmatrix} = \begin{bmatrix} 2ev_1ev_1' & ev_1ev_2' + ev_1ev_3' \\ 2ev_2ev_1' & ev_2ev_2' + ev_2ev_3' \end{bmatrix}$$
(8)

Each entry in the right-hand-side matrix can be represented by a set of triples, e.g.,

$$\left\{ \left[ (1,1),2 \right] \right\} \quad \left\{ \left[ (1,2),1 \right], \left[ (1,3),1 \right] \right\} \\ \left\{ \left[ (2,1),2 \right] \right\} \quad \left\{ \left[ (2,2),1 \right], \left[ (2,3),1 \right] \right\} \right\}$$

and when listed in exit-vertex order for the interleaved-variable order, we have

$$[\{[(1,1),2]\},\{[(1,2),1],[(1,3),1]\},\{[(2,1),2]\},\{[(2,2),1],[(2,3),1]\}].$$
(9)

Now suppose that the two matrices are sub-matrices of level-2 groupings connected by ReturnTuples rt = [5, 2] and rt' = [6, 1, 2], respectively. Then applying  $\langle rt, rt' \rangle$  to Eqn. (9) results in

$$[\{[(5,6),2]\},\{[(5,1),1],[(5,2),1]\},\{[(2,6),2]\},\{[(2,1),1],[(2,2),1]\}].$$
(10)

We call the objects shown in Eqns. (9) and (10) *MatMultTuples*. By this device, the answer to a matrix-multiplication sub-problem (whether from A-connections or B-connections, and at any level  $\geq$  1) can be treated as a multi-terminal CFLOBDD whose value tuple is a MatMultTuple.

Semantics of MatMultTuples. An alternative view of MatMultTuples comes from the right-hand matrix in Eqn. (8): a MatMultTuple is a sequence of bilinear polynomials over the exit vertices of two groupings. We will represent a bilinear polynomial p as a map from exit-vertex pairs to the corresponding coefficient. (The pairs for which the coefficient is nonzero are called the *support* of p. In examples, we show only map entries that are in the support.) In particular, suppose that  $g_1$  and  $g_2$  are two groupings at the same level, with exit-vertex sets EV and EV'. Each entry of a MatMultTuple is of type  $BP_{EV,EV} \stackrel{\text{def}}{=} (EV \times EV') \rightarrow \mathbb{N}$ . (We will drop the subscripts on BP if the exit-vertex sets are understood.)

To perform linear arithmetic on bilinear polynomials, we define

$$\begin{array}{ll}
0_{BP} : BP & 0_{BP} \stackrel{\text{def}}{=} \lambda(ev, ev').0 \\
+ : BP \times BP \to BP & bp_1 + bp_2 \stackrel{\text{def}}{=} \lambda(ev, ev').bp_1(ev, ev') + bp_2(ev, ev') \\
* : \mathbb{N} \times BP \to BP & n * bp \stackrel{\text{def}}{=} \lambda(ev, ev').n * bp(ev, ev')
\end{array}$$

By considering a ReturnTuple to be a map from one exit-vertex set to another, this notation allows us to give a second account of the transformation from Eqn. (9) to Eqn. (10). For instance, let  $rt = [1 \mapsto 5, 2 \mapsto 2]$  and  $rt' = [1 \mapsto 6, 2 \mapsto 1, 3 \mapsto 2]$ . Consider the second element of Eqn. (9):

 $bp = \{[(1, 2), 1], [(1, 3), 1]\} = [(1, 2) \mapsto 1, (1, 3) \mapsto 1]$ . Then the transformation of *bp* induced by *rt* and *rt*' can be expressed as follows (where Eqn. (11) expresses the general case):

$$\langle rt, rt' \rangle (bp) \stackrel{\text{def}}{=} \{ (rt(ev), rt'(ev')) \mapsto bp(ev, ev') \mid ev \in EV, ev' \in EV' \}$$
(11)  
=  $\{ (rt(1), rt'(2) \mapsto bp(1, 2), (rt(1), rt'(3) \mapsto bp(1, 3) \}$   
=  $\{ (5, 1) \mapsto 1, (5, 2) \mapsto 1 \}$ 

At top level, we need a similar operation for the value induced by a pair of value tuples  $\langle vt, vt' \rangle$  (where a value tuple is treated as a map of type  $EV \rightarrow \mathbb{V}$  for a value space  $\mathbb{V}$  that supports + and \*):

$$\langle vt, vt' \rangle (bp) \stackrel{\text{def}}{=} \sum \{ bp(ev, ev') * vt(ev) * vt'(ev') \mid ev \in EV, ev' \in EV' \}$$

Pseudo-code for the matrix-multiplication algorithm can be found as [59, Algs. 19 and 20].

# 7.4 Vector-to-Matrix Conversion

Our approach to vector-matrix multiplication is to convert a vector V of size  $2^n \times 1$  into a matrix M of size  $2^n \times 2^n$ , where V occupies the first column, and all other entries of M are 0. We can then use the matrix-matrix multiplication algorithm presented in §7.3.<sup>14</sup> Note that the CFLOBDD representation of V has n variables and its highest level is log n, whereas the CFLOBDD for matrix M has 2n variables and its highest level is log n + 1.

Let  $x = \langle x_0, x_1, \dots, x_{n-1} \rangle$  denote the variables in the CFLOBDD representation of *V*. The rows of *M* use the same *x* variables; the columns of *M* use a second set of *n* variables:  $y = \langle y_0, y_1, \dots, y_{n-1} \rangle$ . *M* uses the interleaved ordering  $x \bowtie y$ .

 $\begin{array}{ll} Example 7.2. We illustrate the steps of the algorithm using the following example: Consider the vector <math>V = \begin{bmatrix} 2 \\ 3 \\ 5 \\ 0 \end{bmatrix}$  and matrix  $M = \begin{bmatrix} 2 & 0 & 0 & 0 \\ 3 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$ . The goal is to convert V to M. The algorithm constructs intermediate matrices  $M_1$  and  $M_2$  defined as follows:  $M_1 = \begin{bmatrix} 2 & 2 & 2 & 2 \\ 3 & 3 & 3 & 5 \\ 0 & 0 & 0 & 0 \end{bmatrix}$  and  $M_2 = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \end{bmatrix}$ . Finally, the result of converting vector V to a matrix is  $M = M_1 * M_2 = \begin{bmatrix} 2 & 2 & 2 & 2 \\ 3 & 3 & 3 & 5 \\ 0 & 0 & 0 & 0 \end{bmatrix} * \begin{bmatrix} 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{bmatrix}$ , where "\*" denotes pointwise matrix multiplication. (Pseudo-code for the algorithm can be found as [59, Alg. 18].)

# 8 RELATIONS EFFICIENTLY REPRESENTED BY CFLOBDDS

In this section, we prove that there exists an inherently exponential separation between CFLOBDDs and BDDs by showing that there is a family of functions  $f_n$  for which, for all  $n = 2^l$ , the CFLOBDD for  $f_n$  can be exponentially smaller than *any* BDD for  $f_n$ . Note that we do not assume any specific variable ordering when discussing the sizes of BDDs for the functions used to prove the separation. Moreover, our result applies to ROBDDs (in which "don't-care" nodes are removed, and plies are skipped). As a proxy for memory, we use node counts in BDDs, and vertex counts and edge counts in CFLOBDDs. (Recall from footnote 4 that we use "node" solely for BDDs, whereas "groupings" and "vertices"–depicted as the dots inside groupings–refer to CFLOBDDs.)

We show this separation using the family of Hadamard relations, which represent the family  $\mathcal{H}$  of Hadamard matrices discussed in §2 and §3.4. The Hadamard matrices play a role in many quantum algorithms, including the seven that are used in §10.2.2 to evaluate the effectiveness of CFLOBDDs for simulating quantum circuits (namely, GHZ, BV, DJ, Simon's algorithm, QFT, Shor's algorithm, and Grover's algorithm). See §9.2, §10.2.2, and [59, §9.3].

<sup>&</sup>lt;sup>14</sup>Matrix-vector multiplication is performed similarly.

THEOREM 8.1 (EXPONENTIAL SEPARATION FOR THE HADAMARD RELATIONS). The Hadamard relation  $H_n : \{0, 1\}^{n/2} \times \{0, 1\}^{n/2} \rightarrow \{1, -1\}$  between variable sets  $(x_0 \cdots x_{n/2})$  and  $(y_0 \cdots y_{n/2})$ , where  $n = 2^l$ , can be represented by a CFLOBDD with  $O(\log n)$  vertices and edges. In contrast, a BDD that represents  $H_n$  requires  $\Omega(n)$  nodes.

PROOF. *CFLOBDD Claim.* As shown in §3, each matrix  $H_n \in \mathcal{H}$ , where  $n = 2^l$  can be represented by a CFLOBDD with O(l) vertices and edges—i.e., with  $O(\log n)$  space.

BDD Claim. We claim that regardless of the variable ordering, the BDD representation for  $H_n$  requires at least *n* nodes, one node for each variable in the argument. We prove the claim by contradiction. Suppose that there is some BDD *B* for  $H_n$  that does not need at least one node for each variable. In that case, the  $H_n$  function represented by *B* does not depend on that particular variable. Let  $\mathcal{T}$ denote the "all-true" assignment of variables; i.e.,  $\mathcal{T} \stackrel{\text{def}}{=} \forall k \in \{0..n/2 - 1\}, x_k \mapsto T, y_k \mapsto T$ . There are three possible situations:

- Case 1: *B* does not depend on variable  $y_k$ , for some  $k \in \{0..n/2 1\}$ . Consider two variable assignments:  $A_1 \stackrel{\text{def}}{=} \mathcal{T}$  and  $A_2 \stackrel{\text{def}}{=} \mathcal{T}[y_k \mapsto F]$  (i.e.,  $A_2$  is  $A_1$  with  $y_k$  updated to *F*).
- A<sub>1</sub> and A<sub>2</sub> yield the same value for the function represented by *B*, but they yield different values for the Hadamard relation. That is, if  $H_n[A_1] = v$  (where *v* is either 1 or -1), then  $H_n[A_2] = -v$ . We prove this claim by induction on level.
- PROOF. Base Case:
  - *n* = 2. *H*<sub>2</sub>[*A*<sub>1</sub>] is the lower-right corner of Fig. 2a, which is -1, and *H*<sub>2</sub>[*A*<sub>2</sub>] is the value of the path [ $x_0 \mapsto T, y_0 \mapsto F$ ], which yields 1.
- 2130 n = 4.  $A_1$  is the path to the rightmost  $(16^{th})$  leaf in Fig. 2c, which yields a value of 1. For 2131 k = 0,  $A_2$  ends up at the  $12^{th}$  leaf, which is -1; if k = 1,  $A_2$  ends up at the  $15^{th}$  leaf, which is 2132 also -1.
- Induction Step: Let us extend the notation for  $A_1$  and  $A_2$  by adding level information.  $A_1^m$ denotes the "all-true" assignment for  $2^m$  variables, and  $A_2^m = A_1^m[y_k \mapsto F]$ . Let us assume that the claim is true for  $H_{2^m}$ , i.e.,  $H_{2^m}[A_1] = v$  (could be 1 or -1) and  $H_{2^m}[A_2] = -v$ . We must show that the claim holds true for  $H_{2^{m+1}}$ .
- We know that  $H_{2^{m+1}} = H_{2^m} \otimes H_{2^m}$ . Thus,  $H_{2^{m+1}}[A_1^{m+1}] = H_{2^m}[A_1^m] * H_{2^m}[A_1^m]$ , where  $A_1^{m+1} = A_1^m ||A_1^m$ . Thus,  $H_{2^{m+1}}[A_1^{m+1}]$  must have the value  $v^2$  (= v \* v). A recursive relation can similarly be written for assignment  $A_2$ , depending on where the bit-flip for y occurs. There are two possible cases:
  - (1) *k* occurs in the first half;  $A_2^{m+1} = A_2^m ||A_1^m|$  and therefore,  $H_{2^{m+1}}[A_2^{m+1}] = H_{2^m}[A_2^m] * H_{2^m}[A_1^m]$ , which leads to a value of  $-v^2 (= -v * v)$ .
    - (2) *k* occurs in the second half;  $A_2^{m+1} = A_1^m ||A_2^m|$  and therefore,  $H_{2^{m+1}}[A_2^{m+1}] = H_{2^m}[A_1^m] * H_{2^m}[A_2^m]$  which leads to a value of  $-v^2 (= v * -v)$ .
- In both cases, the values obtained with a bit-flip do not match the value for an "all-true" assignment. □
  - We conclude that none of the  $y_k$  variables can be dropped individually.
- Case 2: None of the *x* variables can be dropped individually, using a completely analogous argument to Case 1.

Fig. 14. One-hot encoding of the basis vector  $e_i$  as a decision tree. The single occurrence of 1 is at the leaf indexed by *i*—i.e., at the end of the path from the root that follows the bits of *i*'s representation in binary.

 $H_n[A_2] = H_n[A_3] = H_n[A_4] = -v^2$ , which can be proved using an inductive argument similar to Case 1.) Consequently,  $(x_k, y_k)$  cannot be dropped as a pair.

Because (i) no  $y_k$  can be dropped individually, (ii) no  $x_k$  can be dropped individually, and (iii) no  $(x_k, y_k)$  pair can be dropped, *B*—and hence any BDD that represents  $H_n$ —requires  $\Omega(n)$  nodes.

Unfortunately, we do not have a characterization of relative sizes in the opposite direction (i.e., a bound on CFLOBDD size as a function of BDD size, for all BDDs). It could be that there are families of functions for which BDDs are exponentially more succinct than any corresponding CFLOBDD; however, it could also be that for every BDD there is a corresponding CFLOBDD no more than, say, a polynomial factor larger.

# <sup>2179</sup> 9 APPLICATIONS TO QUANTUM-CIRCUIT SIMULATION <sup>2180</sup>

For certain problems, algorithms run on quantum computers achieve polynomial to exponential speed-ups over their classical counterparts. In this section, we give background on quantum computing (§9.1), summarize the problems used in the experiments in §10.2.2 (§9.2), articulate some advantages of quantum-circuit simulation (§9.3), and discuss the potential of CFLOBDDs (§9.4).

# <sup>2185</sup> 9.1 Background on Quantum Computing

2187 To make the paper self-contained, we briefly summarize the quantum-computing model.

Qubits. In classical computing, a bit is usually thought of as having the value 0 or 1, and the 2188 state of a set of *n* bits  $x_0, \ldots, x_{n-1}$  is a string in  $\{0, 1\}^n$ . A different approach is based on 1-hot 2189 encodings [28]: a bit is either zero, encoded as  $e_0 = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$ , or one,  $e_1 = \begin{bmatrix} 0 & 0 \\ 1 & 1 \end{bmatrix}$ . The states of a two-bit state space would be encoded as follows:  $e_{00} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \\ 1 & 0 \end{bmatrix}$ ,  $e_{01} = \begin{bmatrix} 0 & 0 \\ 1 & 0 \\ 1 & 0 \end{bmatrix}$ ,  $e_{10} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 \\ 1 & 0 \end{bmatrix}$ , and  $e_{11} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 \\ 1 & 0 \end{bmatrix}$ . 2190 2191 2192 Quantum-computing generalizes the second approach: a *qubit* can have a value such as  $\int_{\alpha_1}^{\alpha_2} \left[ \frac{\alpha_0}{\alpha_1} \right]$ 2193 where  $\alpha_0$  and  $\alpha_1$  are complex numbers, called *amplitudes*, such that  $|\alpha_0|^2 + |\alpha_1|^2 = 1$ ; that is, a qubit 2194 is a complex unit vector in a vector space with basis vectors  $e_0$  and  $e_1$ . For two qubits, the basis 2195 vectors are  $e_{00}$ ,  $e_{11}$ ,  $e_{10}$ , and  $e_{11}$ , and the state space consists of the complex unit vectors of the form 2196  $\begin{bmatrix} \alpha_{00} \\ \alpha_{01} \\ \alpha_{10} \\ \vdots \end{bmatrix}$ , where  $|\alpha_{00}|^2 + |\alpha_{01}|^2 + |\alpha_{10}|^2 + |\alpha_{11}|^2 = 1$ . In general, an *n*-qubit space consists of the complex 2197 2198 unit vectors in a  $2^n$ -dimensional space, and a quantum state can have non-zero amplitudes for all 2199  $2^n$  basis vectors. The decision tree for the one-hot encoding of a basis vector  $e_i$ ,  $0 \le i \le 2^n - 1$ , of 2200 such a  $2^n$ -dimensional space is depicted in Fig. 14. 2201

2202 *Quantum circuits*. A *quantum circuit* takes as input an initial quantum-state vector, and applies a 2203 sequence of *quantum gates*, which are each length-preserving transformations, and can be expressed 2204 as unitary matrices. Thus, quantum-circuit simulation requires a way to perform linear algebra 2205

with vectors of size  $2^n$  and matrices of size  $2^n \times 2^n$ , where *n* is the number of qubits involved. 2206 Examples of gates that operate on single qubits are  $I = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$ ,  $H = \frac{1}{\sqrt{2}} \begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$ , and  $X = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$ . I 2207 2208 leaves a quantum state as is; the Hadamard gate H sends a basis state to a state in "superposition" 2209 (i.e., a state that is a non-trivial linear combination of basis states);<sup>15</sup> X complements the indices of 2210 a qubit's basis states, and thus flips the positions of the amplitudes, sending  $\begin{bmatrix} 0 & \alpha_1 \\ \alpha_1 \end{bmatrix} \begin{bmatrix} \alpha_1 & \alpha_2 \\ \alpha_2 \end{bmatrix}$ . Let 2211 k occurrences of M 2212

 $M^{\otimes k}$  denote the *k*-fold Kronecker product of *M* with itself:  $M^{\otimes k} = M \otimes M \otimes \ldots \otimes M$ . The quantum gate that, e.g., applies *H* to the *j*<sup>th</sup> qubit of an *n*-qubit quantum state is  $I^{\otimes (j-1)} \otimes H \otimes I^{\otimes (n-j)}$ .

Measurement and Entanglement. A measurement operation samples a basis vector based on the distribution given by the squares of the absolute values of the amplitudes. Qubits are said to be entangled if the measurement of one qubit can influence the result obtained by measuring a different qubit. A Controlled-NOT (CNOT) gate operates on two index bits: one bit is the control-bit and the other is the controlled-bit; in the output, the value of the controlled-bit is flipped if the control-

bit is '1.' For two qubits, with the first qubit as the control-bit, the gate's matrix is  $\begin{bmatrix} 0 & 0 & 0 & 1 & 0 & 1 \\ 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 1 \end{bmatrix}$ **Г**1 **Т** 

For instance, 
$$CNOT \times \begin{pmatrix} 0 \\ 1 \\ \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \end{bmatrix} \otimes \begin{pmatrix} 0 \\ 1 \\ 0 \\ \frac{1}{\sqrt{2}} \end{bmatrix} = CNOT \times \begin{pmatrix} 0 \\ 0 \\ 1 \\ \frac{1}{\sqrt{2}} \\ 0 \\ 11 \\ \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \end{bmatrix} = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 11 \\ \frac{1}{\sqrt{2}} \\ \frac{1}{\sqrt{2}} \end{bmatrix}$$
. The latter state is entangled:

measuring either (or both) qubits yields either the state  $e_{00}$  or  $e_{11}$ , each with probability  $\frac{1}{2}$ . In other words, after measuring either qubit and obtaining a value  $v \in \{0, 1\}$ , the value of the other qubit must also be v.

#### 9.2 Quantum Algorithms

This section describes the quantum-computation problems that are used in the experiments in \$10.2.2. More details about the algorithms for these problems can be found in [59, §9.3]

The Greenberger-Horne-Zeilinger (GHZ) state. The GHZ state is the following entangled state vector over 3 qubits (i.e., a unit vector of size 8):  $GHZ_3 = \frac{1}{\sqrt{2}} [10000001]^T$ . We extend the concept to *n* qubits by defining  $GHZ_n = \frac{1}{\sqrt{2}} [100...001]^T$ , which is a unit vector of size  $2^n$ .

The Bernstein-Vazirani (BV) problem. Given an oracle that implements a function  $f: \{0, 1\}^n \rightarrow 0$  $\{0,1\}$  in which f(x) is promised to be the dot product, mod 2, between x and a secret string  $s \in \{0, 1\}^n$ -i.e.,  $f(x) = x_1 \cdot s_1 \oplus x_2 \cdot s_2 \oplus \cdots \oplus x_n \cdot s_n$ -find s.

The Deutsch-Jozsa (DJ) problem. Given an oracle that implements a function  $f : \{0, 1\}^n \to \{0, 1\}$ , where f is promised to be either a constant function (0 on all inputs or 1 on all inputs) or a balanced function (returns 1 for half of the input domain and 0 for the other half), determine if f is balanced or constant.

Simon's problem. Given a function  $f: \{0,1\}^n \to \{0,1\}^n$ , where f is promised to satisfy the property that there is a "hidden vector"  $s \in \{0, 1\}^n$  such that, for all x and y, f(x) = f(y) if and only if  $x = y \oplus s$ , find the hidden vector *s*.

Quantum Fourier Transform (QFT). The QFT is a linear transformation that, in matrix form,

 $\begin{bmatrix} 1 & 1 & 1 & 1 & \dots & 1 \\ 1 & \omega & \omega^2 & \omega^3 & \dots & \omega^{N-1} \\ 1 & \omega^2 & \omega^4 & \omega^6 & \dots & \omega^{2(N-1)} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \end{bmatrix}, \text{ where } N = 2^n \text{ and } \omega = e^{2\pi i/N}. \text{ The }$ has the following form:  $\begin{bmatrix} \cdot & \cdot & \cdot \\ 1 & \omega^{N-1} & \omega^{2(N-1)} & \omega^{3(N-1)} & \dots & \omega^{(N-1)(N-1)} \end{bmatrix}$ 

problem to be solved is to apply the QFT matrix to a given quantum-state vector.

Shor's algorithm. The problem is to find prime factors of a given integer K, where  $0 \le K \le 2^n - 1$ . 2255 Grover's algorithm. The problem to be solved is the following search problem: given a function 2256  $f: \{0, 1, \dots, 2^n - 1\} \rightarrow \{0, 1\}$  such that there is a unique x for which f(x) = 1, find x. 2257

#### 9.3 **Advantages of Simulation**

Simulation of a quantum circuit can have advantages compared to actually running a circuit on a quantum computer. Quantum simulation has a role in testing quantum computers. In particular, simulation can be used to create test suites for checking the correctness of the output states and measurements obtained from physical hardware. However, current quantum computers are errorprone, due to noise, and hence bad for confirming the correctness of a quantum algorithm. In contrast, a simulation never produces incorrect results (modulo floating-point round-off error and bugs in the implementation of the simulator).

Moreover, a simulation can deviate from certain requirements of the quantum-computation model and perform the simulation in a way that no quantum device could.

- (1) Some quantum algorithms perform multiple iterations of a particular quantum operator Op (e.g., k iterations, where k is some power of 2). A simulation can operate on Op itself [72, Ch. 6], using repeated squaring to create the sequence of derived operators  $Op^2$ ,  $Op^4$ ,  $Op^8, \ldots, Op^{2^{\log k}} = Op^k$ , which can be accomplished in log k iterations. The final answer is then obtained using  $Op^k$ . A physical quantum computer can only apply Op sequentially, and thus must perform k applications of *Op*. This approach is particularly useful in simulating Grover's algorithm.
- (2) The quantum-computation model requires the use of a limited repertoire of operations: every operation is a multiplication by a unitary matrix, and all results (and all intermediate values) must be produced in this way. In contrast, it is acceptable for a simulation to create some intermediate results by alternative pathways. In some cases, our simulation of a quantum algorithm directly creates a CFLOBDD that represents an intermediate value, thereby avoiding a sequence of potentially more costly computational steps that stay within the quantum model. (See "A Special-Case Construction" in [59, §9.2.5], which is used in Grover's algorithm.)
- 2284 (3) In many quantum algorithms, the final state needs to be measured multiple times. When 2285 running on a physical quantum computer, part or all of the quantum state is destroyed after 2286 each measurement of the state, and thus the quantum steps must be re-performed before each successive measurement. In contrast, in a simulation the quantum steps need only be 2288 performed once. At that point, there are two possibilities:
  - Once we have the final quantum state produced by the simulation in hand, one can inspect the amplitudes and thereby avoid doing any measurement at all.
- 2291 • If the goal of the simulation is to confirm that a given measurement protocol is correct, 2292 then because a simulated measurement does not cause any part of the simulated quantum 2293 state to be lost, multiple measurements can be made-e.g., using the sampling algorithm 2294 given in §6.4.2-without having to re-perform the steps of the quantum computation before 2295 each successive measurement.

Quantum supremacy refers to a computing problem and a problem size beyond which the problem 2297 can be solved efficiently on a quantum computer, but not on a classical computer. Quantum 2298 simulation is at one of the borders between classical computing and quantum computing: in 2299 a simulation, a classical computer performs the computation in roughly the same manner as a 2300 quantum computer, but can take advantage of shortcuts of the kind listed above. In principle, a more 2301 efficient simulation technique has the potential to change the threshold for quantum supremacy. 2302

#### The Potential of CFLOBDDs for Quantum-Circuit Simulation 2304 9.4

2305 A quantum state  $\sum_{w \in \{0,1\}^{2^n}} \alpha_w \cdot e_w$  is a function of type  $\{0,1\}^n \to \mathbb{C}$ , and thus could be encoded with 2306 a decision tree of height n. Such a representation would be inefficient. The potential of CFLOBDDs 2307 is for providing (up to) double-exponential compression in the sizes of the vectors and matrices 2308 that arise during quantum simulation using  $\log n$  and  $\log n + 1$  levels, respectively. Because many 2309 quantum gates can be described using Kronecker products, there is great potential for them to have 2310 a compact representation as a CFLOBDD. 2311

The following table indicates where to find details about the CFLOBDD operations needed to simulate a quantum circuit:

#### 2327 **10 EVALUATION**

2328 In this section, we explain our experimental setup and describe the experiments we carried out, which were 2329 designed to address the following research questions:

2330 RO1: Do theoretical guarantees of *double-exponential compression* by CFLOBDDs allow them to represent 2331 substantially larger Boolean functions than BDDs?

2332 **RQ2:** Do CFLOBDDs outperform BDDs when used for quantum simulation (in terms of time and space)?

#### 10.1 Experimental Setup 2334

We compared our implementation of CFLOBDDs<sup>16</sup> against a widely used BDD package, CUDD [60] (version 2335 3.0.0), using CUDD's C++ interface. The metrics are (i) execution time, and (ii) space (node counts in the case 2336 of BDDs; vertex counts + edge counts in the case of CFLOBDDs). We ran all experiments on AWS machines: 2337 t2.xlarge machines with 4 vCPUs, 16GB of memory, and a stack size of 8192KB, running on Ubuntu OS. For RQ1 2338 (§10.2.1), we used a collection of synthetic benchmarks, and compared the performance of CFLOBDDs against 2339 (i) CUDD with a static variable ordering (similar to the one used in the CFLOBDDs), (ii) CUDD with dynamic 2340 variable reordering, and (iii) Sentential Decision Diagrams (SDDs) [18] (which can also be exponentially more 2341 succinct than BDDs), using Python package PySDD [41] (version 0.1). For RQ2 (§10.2.2), we used a set of 2342 quantum-simulation benchmarks, and again compared the performance of CFLOBDDs against CUDD. For the 2343 quantum benchmarks, we did not enable dynamic variable reordering for BDDs because we could not retrieve 2344 the correct order of the output bits for a sampled string.

Five of the quantum benchmarks-BV, DJ, Simon's algorithm, Shor's algorithm, and Grover's algorithm-use 2345 oracles that either directly or indirectly incorporate the answer sought. Our methodology is standard for 2346 quantum-simulation experiments. Each benchmark uses a pre-processing step to create the CFLOBDD/BDD 2347 that represents the oracle. In each run, an answer is first generated randomly, and then the CFLOBDD/BDD 2348 that represents the oracle is constructed. Knowledge about the answer is used only during oracle construction. 2349 Thereafter, the quantum algorithm proper is simulated; these steps have no access to the pre-chosen answer 2350

<sup>16</sup> The implementation is available at https://github.com/trishullab/cflobdd. 2351

(other than the ability to perform operations on the oracle, treated as a unitary matrix). The final step ofrunning the benchmark is to check that the quantum algorithm obtained the correct answer.

We could not run the quantum benchmarks with SDDs because SDDs do not support multi-terminal values.
 However, we ran the quantum benchmarks using Quimb [24], a quantum-simulation library that uses tensor
 networks.

For the RQ2 experiments, we had to extend CUDD in two ways (for details, see [59, §10.1]):

- (1) CUDD supports algebraic decision diagrams (ADDs), which are multi-terminal BDDs with a value from a semiring at each terminal node. To support functions of type  $\{0, 1\}^n \to \mathbb{C}$ , we needed a semiring that was not part of the standard CUDD distribution. We implemented a semiring of multi-precisionfloating-point [20] complex numbers. For the corresponding experiments with CFLOBDDs, we used the same semiring for the terminal values of CFLOBDDs.
- (2) To allow quantum measurements to be carried out, we extended ADDs to support path sampling (i.e., selection of a path, where the probability of returning a given path is proportional to a function of the path's terminal value).

### 2367 10.2 Benchmarks and Experimental Results

10.2.1 RQ1: Do theoretical guarantees of double-exponential compression by CFLOBDDs allow them to
 represent substantially larger Boolean functions than BDDs? We used the following three benchmarks to
 compare the execution time and memory usage (as vertex count + edge count) of CFLOBDDs against BDDs
 and SDDs.

•  $XOR_n = \bigoplus_{i=1}^n x_i$ 

- $MatMult_n = (H_nI_n + X_nH_n + I_nX_n)$ , where  $H_n$  is the Hadamard matrix,  $I_n$  is the Identity matrix, and  $X_n$  is the NOT matrix of size  $2^{n-1} \ge 2^{n-1}$ . (The aim of the benchmark is to test the performance of the matrix-multiplication and addition operations.)
- $ADD_n(X, Y, Z) \stackrel{\text{def}}{=} Z = (X + Y \mod 2^{n/4})$ , where X, Y, and Z are n/4-bit integers.

2377 Tab. 2 shows the performance of CFLOBDDs, BDDs (both with and without dynamic variable-reordering 2378 enabled), and SDDs within the 15-minute timeout threshold. For the two kinds of BDD experiments and 2379 the SDD experiments, we used a stack size of 1GB. For the ADD benchmark, BDDs (both with and without 2380 dynamic reordering) and SDDs ran out of memory within the 15-minute timeout threshold for problems with sufficiently many variables, even with such a large stack. (BDDs with dynamic reordering produced 2381 out-of-memory errors for #variables  $\geq 2^{24}$ : the first step in the computation is to allocate the variables, which 2382 by itself leads to memory exhaustion for  $2^{24}$  variables and beyond.) Note that, for SDDs, benchmark  $MatMult_n$ 2383 is not applicable because SDDs do not handle non-Boolean values. 2384

Because of a slightly technical alignment issue, our CFLOBDD representations of  $ADD_n$  deliberately waste one-quarter of the Boolean variables (as *dummy variables*). To make a fair comparison, our BDD and SDD encodings of  $ADD_n$  use only three-quarters of the Boolean variables indicated in column two of Tab. 2.

2387 To understand how large a Boolean function could be created using CFLOBDDs (as a function of the 2388 number of Boolean variables),<sup>17</sup> we also measured the performance of the CFLOBDD implementation on 2389 the micro-benchmarks using a timeout of ninety minutes. Fig. 15 shows graphs of size (#vertices + #edges) and time versus the number of Boolean variables for the three benchmarks.<sup>18</sup> Fig. 15a shows the graphs for 2390 XOR<sub>n</sub>. In these graphs, time is in seconds, and the number of Boolean variables is on a log scale. We were able 2391 to construct  $XOR_n$  with up to  $2^{22} = 4,194,304$  variables. Fig. 15b and Fig. 15c show the graphs for  $MatMult_n$ 2392 and  $ADD_n$ , respectively. In these graphs, time is in milliseconds, and the number of Boolean variables is 2393 on a log scale for MatMult<sub>n</sub> and a log log scale for ADD<sub>n</sub>. We were able to construct MatMult<sub>n</sub> with up to 2394  $2^{27} = 134,217,728$  variables and  $ADD_n$  with up to  $2^{2^{23}} = 2^{8,388,608} \approx 4.27 \times 10^{2,525,222}$  variables, which comes 2395 to  $0.75 \times 2^{8,388,608} \approx 3.12 \times 10^{2,525,222}$  after removing dummy variables. 2396

<sup>2397</sup> 

 $<sup>^{2398}</sup>$  <sup>17</sup>The stack size was increased to 1GB for the runs with more than  $2^{2^{15}}$  Boolean variables.

 $<sup>^{18}</sup>$  Tab. 2 shows the comparison of CFLOBDDs, BDDs, and SDDs for examples with a 15-minute timeout. In contrast, Fig. 15 shows the results of the stress test that we performed, where we gave the CFLOBDD implementation a 90-minute timeout.

Table 2. Performance of CFLOBDDs against BDDs, BDDs with dynamic reordering, and SDDs on the synthetic benchmarks for different numbers of Boolean variables. (For the two kinds of BDD experiments and the SDD experiments, we used a stack size of 1GB.)

Findings. CFLOBDDs performed better than BDDs and SDDs, both in terms of time and memory. For the benchmarks with more than 2<sup>18</sup> Boolean variables, BDDs had memory issues. Using CFLOBDDs, it was also possible to construct representations of the benchmark functions with astounding numbers of Boolean variables:  $2^{22} = 4,194,304$  for XOR<sub>n</sub>;  $2^{27} = 134,217,728$  for MatMult<sub>n</sub>; and  $0.75 \times 2^{8,388,608} \approx 3.12 \times 10^{2,525,222}$ for  $ADD_n$ . These results support the claim that CFLOBDDs can provide substantially better compression of Boolean functions than BDDs.

10.2.2 RQ2: Do CFLOBDDs outperform BDDs when used for quantum simulation (in terms of time and space)? Tabs. 3 and 4 show the performance of CFLOBDDs and BDDs when simulating several well-known quantum algorithms. In each case, for both CFLOBDDs and BDDs, we used the interleaved-variable ordering.

For GHZ, the algorithms do not depend on an input; the output is solely a function of the number of qubits used. We used the quantum circuit given by Yu and Palsberg [70, \$2] for obtaining the GHZ state for *n* qubits; see also [59, §9.3.1]. For BV, DJ, QFT, Simon's algorithm, Shor's algorithm, and Grover's algorithm, we ran each algorithm with 50 different randomly selected inputs, for each of the indicated number of qubits. Tabs. 3 and 4 report the average vertex and average edge counts (for CFLOBDDs), average node count (for BDDs), and 2447 average time taken. In the case of Simon's algorithm, CFLOBDDs timed-out on 9 of the 50 test cases, whereas BDDs timed-out on 28 of the 50 test cases; we report the average counts and average times for the test cases 2448 that did not time out. BV, DJ, Simon's algorithm, Shor's algorithm, and Grover's algorithm make use of oracles 2449

2437

created during a pre-processing step (see also 10.1); we do not include the time for oracle construction in the execution time, but we do include it as part of the 15-minute/90-minute timeout threshold. For the case of QFT, the input is one of the basis vectors selected randomly. For 16 qubits and a timeout threshold of 15 minutes, QFT ran to completion in 11 of the 50 runs. The numbers reported in Tab. 4 are the averages for the 11 successful runs. In the entries for Shor's algorithm, *N* is the number being factored, and *a* is the value used in the associated "order-finding problem."<sup>19</sup>

Table 4. Table (cont.) of the performance of CFLOBDDs against BDDs for increasing numbers of qubits.

In several cases, the problem sizes that completed successfully using CFLOBDDs were dramatically larger than the sizes that completed successfully using BDDs. With a 15-minute timeout, the number of qubits that CFLOBDDs can handle are 65,536 for GHZ, 524,288 for BV; 4,194,304 for DJ; and 4,096 for Grover's Algorithm, besting BDDs by factors of 128×, 1,024×, 8,192×, and 128×, respectively.

We also ran the CFLOBDD simulations with a 90-minute timeout, both to understand how execution time scales, as a function of number of qubits, and to see how large a problem instance can be handled. Fig. 16 shows the time taken (in seconds), with increasing numbers of qubits, for BV, GHZ, and DJ. With a 90-minute timeout, the BV and GHZ algorithms ran to completion with  $2^{20} = 1,048,576$  qubits, and the DJ algorithm ran to completion with  $2^{21} = 2,097,152$  qubits.

For both CFLOBDDs and BDDs, the transition from a problem size that completes successfully to a problem size that fails is rather abrupt. For all of the problems, the time reported for the CFLOBDD run with the largest number of qubits that completes successfully is well under 15 minutes. Unfortunately, for the next larger run, oracle construction timed out after 15 minutes for the BV and DJ algorithms, and as a result we terminated the entire algorithm. For Grover's algorithm, the number of bits for the floating-point representation is 100 for all runs, except for those with 2,048, 4,096, and 8,192 qubits, for which we used 500, 750, and 1,000 bits, respectively. The increased cost of floating-point operations slows down matrix multiplications in Grover's algorithm, causing the 8,192-qubit run to exceed 15 minutes.

Findings. For smaller numbers of qubits, the more-complex nature of the data structures used in CFLOBDDs resulted in slower execution times than with BDDs. However, CFLOBDDs scaled much better than BDDs as the number of qubits increased, both in terms of memory (i.e., vertices + edges for CFLOBDDs, nodes for BDDs) and execution time. In some cases, the problem sizes that completed successfully using CFLOBDDs were dramatically larger than the sizes that completed successfully using BDDs. In particular, the number of qubits that could be handled using CFLOBDDs was larger-compared to BDDs-by a factor of 128× for GHZ; 1,024× for BV; 8,192× for DJ; and 128× for Grover's algorithm.

Fig. 16. Execution time (in seconds) vs. number of qubits (on a log scale) for three of the benchmarks.

*Intermediate swell.* For many of the algorithms, the initial and final CFLOBDD and BDD structures are of reasonable size, but there is an intermediate swell as the algorithm runs. Figs. 17 and 18 show how size evolves in the various steps of five of the algorithms during the CFLOBDD-based and BDD-based simulations. The figures show how size evolves for all 50 runs, along with the average value at every step (highlighted in black). Fig. 18 shows that the CFLOBDD simulation of Grover's algorithm uses constant space from steps 3 to 15. The explanation is that, although the state vector changes at each step, the size of the CFLOBDD representation of the state vector does not change.

*Comparison with Tensor Networks.* We also compared the performance of CFLOBDDs with Quimb [24], a state-of-the-art quantum simulator. Tab. 5 shows the performance of our CFLOBDD implementation and Quimb on the previously discussed quantum benchmarks. For the Quimb-based simulations of GHZ, BV, DJ, and Grover's algorithm, we used Matrix Product States (MPSs) [7, 63] and Matrix Product Operators (MPOs) [62] in algorithms modeled after the ones described in [68]. For Simon's algorithm, we noticed that directly creating a circuit and performing contraction using Quimb led to better scalability than using MPS/MPOs. For QFT, we tried both the standard circuit [49] and the nearest-neighbor circuit mentioned in [21]. We found that the Quimb-based simulation results for both circuits are very similar, and only the former are reported here. For Shor's algorithm, we use the 2n + 3 circuit from [8], but the internal gates are created directly, as mentioned in [68] (and hence the circuit only has 2n + 1 qubits). For Grover's algorithm, we found that the maximum number of qubits that can be simulated using Quimb with a 15-minute timeout is 29 qubits.<sup>20</sup>

These experiments show that, on some of the benchmarks, CFLOBDDs scale to much larger problem sizes than the Quimb tensor-network package, but on other benchmarks Quimb performs much better than CFLOBDDs.

 $<sup>^{20}</sup>$  With 32 qubits, Quimb takes 1496.6sec  $\approx$  25min.

<sup>,</sup> Vol. 1, No. 1, Article . Publication date: December 2023.

What allows CFLOBDDs to perform so well on Grover's algorithm? In each run of the CFLOBDD simulation of Grover's algorithm, a random 4096-bit string *s* is chosen, then the Grover oracle matrix is constructed, along with the Grover diffusion operation, which are then multiplied together. A version of Grover's algorithm based on repeated squaring of the product matrix is carried out (via operations that use the cumulative-product

(b) Simon's algorithm to qubits

Fig. 18. Evolution of size through the steps of the indicated algorithms. (Left: CFLOBDD-based simulation; right: BDD-based simulation.)

matrix—which depends on s—but the operations are oblivious to the value of s itself); the algorithm's answer s' is retrieved; and finally s and s' are compared to make sure that the computed result is correct.

The reason that this process is space-efficient is that the Grover oracle is basically a "-1 hot encoding" of s, 2731 and thus can be constructed by an algorithm that is a mixture of the principles used in the algorithms for 2732 constructing the representations of (i) projection functions (§6.1.2), and (ii) the identity matrix ([59, §9.2.2 and 2733 Alg. 24]). In the largest cases of Grover's algorithm that completed successfully within 15 minutes, the matrix 2734 has dimensions  $2^{4096} \times 2^{4096}$ ; all off-diagonal entries are 0; and all diagonal entries are 1 except for the (s, s)2735 entry, which is -1. To represent this matrix, one needs  $8,192 = 2^{13}$  Boolean variables: 4,096 for the row-index and 2736 4,096 for the column-index. There is a CFLOBDD representation of this matrix whose highest-level grouping 2737 is at level 13-thus, there are 14 levels in total, counting level 0. Moreover, the CFLOBDD has only a constant 2738 number of groupings at each of the 14 levels, so the matrix is one for which the CFLOBDD representation 2739 exhibits double-exponential compression.

Although multiplication of matrices represented by CFLOBDDs is not particularly efficient (see the last row of Tab. 1), there is little or no infill caused by the repeated-squaring operations, and so the matrix representation has only a limited amount of intermediate swell. (See the left-hand graph in Fig. 18(a) for a plot of memory usage for the CFLOBDD implementation of Grover's algorithm for 16 qubits.)

### 2794 11 RELATED WORK

2795 CFLOBDDs were devised in the late 1990s; however, except for a rejected US patent application posted on the 2796 USPTO site in 2002 [56], nothing about them has ever been published. Work on them was abandoned in 2002 due to not having found an application on which CFLOBDDs performed better than BDDs-other than some 2797 of the recursively defined spectral transforms, such as the Reed-Muller, inverse Reed-Muller, Hadamard, and 2798 Boolean Haar wavelet transforms [32]. In a 2009 blog post [38], Lipton sketched a proposal for Pushdown BDDs, 2799 a BDD-like structure based on NPDAs. CFLOBDDs are closely related-they are based on DPDAs, rather than 2800 NPDAs-which caused us to re-examine what relations CFLOBDDs could represent efficiently, and to discover 2801 that  $ADD_n$  was such a relation [59, §8.3]. This paper combines the material from the patent application with 2802 our recent results on quantum simulation. 2803

The idea behind CFLOBDDs was inspired by an obstacle encountered in interprocedural path profiling [44]. 2804 In generalizing the Ball and Larus intraprocedural path-profiling scheme [4] to allow profiling of path fragments 2805 that cross procedure boundaries, Melski and Reps found that an acyclic, non-recursive, interprocedural control-2806 flow graph of size k could have  $2^{2^k}$  matched paths. For instance, Melski [42] found that one 20,000-line program 2807 had 2<sup>400,000</sup> such paths—which would require the instrumentation code to manipulate 400,000-bit numbers! 2808 From here, it was only a short distance to CFLOBDDs-how to interpret such graphs as representations of 2809 Boolean functions; how to implement the operations of a BDD-like API; how to maintain canonicity; etc. The feature that threatened to sink the path-profiling scheme-double-exponential explosion-became the linchpin 2810 of a double-exponentially compressed representation of Boolean functions. 2811

Over the years, many variants of BDDs have been proposed [57]. These data structures can be broadly divided into three families: ones that make use of weights on edges, ones that do not use edge weights, and ones that allow the underlying graph to have cycles.

Examples of (acyclic) edge-weighted BDD variants include EVBDDs [36] and FEVBDDs [61]. If the weights are allowed to be unboundedly large, a polynomial-sized data structure of this sort can be used to encode a decision tree that is double-exponentially larger. However, to the best of our knowledge, such double-exponential compression is impossible when the weights are required to use a constant number of bits.

Unweighted BDD variants include Multi-Terminal BDDs [13, 15], Algebraic Decision Diagrams [3], Free Binary Decision Diagrams (FBDDs) [64, §6], Binary Moment Diagrams (BMDs) [12], Hybrid Decision Diagrams (HDDs) [14], Differential BDDs [2], and Indexed BDDs (IBDDs) [33]. Several of these BDD variants offers exponential compression over classical BDDs. However, because FBDDs, BMDs, HDDs, and IBDDs that encode, e.g., the identity function, need to examine each variable, the exponential-separation argument for CFLOBDDs from §8 carries over for all of these variants.

Cyclic BDD variants include Linear/Exponentially Inductive Functions (LIFs/EIFs) [26, 27] and Cyclic BDDs (CBDDs) [52].

The differences between CFLOBDDs and these representations can be characterized as follows:

• The aforementioned representations all make use of numeric/arithmetic annotations on the edges of the graphs used to represent functions over Boolean arguments, rather than the matched-path principle that is the basis of CFLOBDDs. Matched paths can be characterized in terms of a context-free language of matched parentheses, rather than in terms of numbers and arithmetic (see Eqn. (1)).

• An essential part of the design of LIFs and EIFs is that the BDD-like subgraphs in them are connected in very restricted ways. In contrast, in CFLOBDDs, different groupings at the same level (or different levels) can have very different kinds of connections in them.

- Similarly, CBDDs require that there be some fixed BDD pattern that is repeated over and over in the structure; a given function uses only a few such patterns. With CFLOBDDs, there can be many reused patterns (i.e., in the lower-level groupings in CFLOBDDs).
- CBDDs are not canonical representations of Boolean functions, which complicates the algorithms for performing certain operations on them, such as the operation to determine whether two CBDDs represent the same function.
- The layering in CFLOBDDs serves a different purpose than the layering found in LIFs/EIFs and CBDDs.
   In the latter representations, a connection from one layer to another serves as a jump from one BDD-like fragment to another BDD-like fragment. In CFLOBDDs, only the lowest layer (i.e., the collection of

59

level-0 groupings) consists of BDD-like fragments (and just two very simple ones at that); it is only at level 0 that the values of variables are interpreted. As one follows a matched path through a CFLOBDD, the connections between the groupings at levels above level 0 serve to encode which variable is to be interpreted next.

<sup>2847</sup> LIFs/EIFs/CBDDs could be generalized by replacing BDD-like subgraphs in them with CFLOBDDs.

2848 Other data structures that generalize BDDs are Sentential Decision Diagrams (SDDs) [18] and Variable Shift SDDs (VS-SDDs) [47]. These data structures generalize BDDs by assuming a tree-shaped ordering over 2849 variables, and there are functions for which these data structures offer double-exponential compression over 2850 decision trees and an exponential compression over BDDs. In CFLOBDDs, a grouping q can have multiple 2851 middle vertices that reuse the same B-connection grouping b, as long as the return edges for the different 2852 invocations of b use different mappings to q's exit vertices. This "contextual rewiring" gives CFLOBDDs greater 2853 ability to reuse substructures than SDDs and VS-SDDs. (Moreover, b can also be used as the A-connection 2854 grouping of q.) SDDs and VS-SDDs (and their quantitative generalizations, such as Probabilistic SDDs [34]) 2855 have not, so far, been used in matrix computations, and implementations of operations such as Kronecker 2856 product and matrix multiplication based on these structures are unknown, which meant that we could not 2857 use them in our quantum-simulation experiments. We did compare CFLOBDDs against SDDs for two of the 2858 micro-benchmarks, and found that CFLOBDDs were much faster (Tab. 2). However, the relationship between 2859 these representations and CFLOBDDs merits future study.

2860 Also related are prior methods for quantum simulation. Such simulation can be exact or approximate; our focus here is on exact simulation (modulo floating-point round-off error). Decision diagrams used for such 2861 simulation include QMDDs [46, 71] and TDDs [29]. Both of these are weighted BDD representations, and hence 2862 cannot be compared in an apples-to-apples way with CFLOBDDs, which are unweighted representations (i.e., 2863 the edges of a CFLOBDD do not have associated weights). However, to understand the potential of CFLOBDDs, 2864 we mention here how our experimental results with CFLOBDDs compare with the published data for QMDDs: 2865 CFLOBDDs perform better than the best published numbers on some algorithms (GHZ, BV, DJ, Grover) and 2866 worse on others (OFT, Shor) [72, Tab. 5.1].<sup>21</sup> We also compared our approach to tensor networks, a widely 2867 used approach to quantum simulation that is not based on decision diagrams. As shown in Tab. 5, CFLOBDDs 2868 perform better than tensor networks on some algorithms (GHZ, BV, DJ, Grover) and worse on others (Simon, 2869 QFT, Shor).

Similar to the well-known quantum algorithms discussed in this paper, variational quantum algorithms,
which include a noise channel, can also be simulated using CFLOBDDs. Huang et al. [31] simulate variational
quantum algorithms using knowledge-compilation techniques. In their approach, the noise component is
modeled as an additional operator whose action is represented as a matrix. The noise matrix can be represented
as a CFLOBDD, and hence CFLOBDDs can also be used for simulating variational quantum algorithms.

2875 Compression of Programs and Compression Principles. A CFLOBDD can compactly represent many finite 2876 paths. This property is akin to a statement that the use of nonrecursive procedures in programs can enable 2877 small programs to have many execution paths, and is the essence of the aforementioned observation by Melski 2878 and Reps that an acyclic, non-recursive, interprocedural control-flow graph of size k could have  $2^{2^k}$  matched 2879 paths. Although not formulated as a theorem, this observation was stated in Melski's Ph.D. thesis [43, §3.5.4]. 2880 Melski uses Yannakakis's notion of *L*-reachability [69] (i.e., a path from node *s* to node *t* only counts as a valid 2881 s-t connection if the path's labels form a word in L), and defines the notion of a "finite-path graph" with respect 2882 to some language L: there are only a finite number of L-paths from, e.g., program entry to program exit [43, §3.4]. He then defines an interprocedural control-flow graph, denoted by  $G_{fin}^*$ . One of the languages of interest 2883 is the language of unbalanced-left paths [44, §2.1], in which each return-edge is matched with the closest 2884 preceding unmatched call-edge, but there can be zero or more umatched call-edges. (The unbalanced-left 2885 language is typically the language of interest for context-sensitive interprocedural dataflow analysis [53, 55].) 2886

<sup>2887</sup> 

<sup>2888</sup> 

<sup>&</sup>lt;sup>21</sup>Note that the number of qubits for Shor's algorithm reported in [72, Tab. 5.1] is the number of qubits of the circuit, whereas in Tabs. 4 and 5, #Qubits is the number of bits of the number N being factored, where #*Qubits*-of-circuit = 2 \* #bits-of-N.

Melski observes, "... the number of [unbalanced-left] paths through  $G^*_{fin}$  can be doubly exponential in the size 2892 of  $G^*_{fin}$ ." <sup>22</sup> 2893

2894 These results are tantamount to the statement (proposed by one of the referees) that "there is a family 2895 of programs  $P_n$ , written with non-recursive procedures, that each would be exponentially larger if written 2896 without non-recursive procedures." In the 1970s, the literature on program schematology [50] explored the relative power of various programming constructs, beginning with results showing that recursive procedure 2897 calls are more expressive than iteration (in particular, there are recursive program schemes such that, for 2898 2899 some interpretation of the function and predicate symbols, any flowchart scheme will produce results that are different from those obtained with the recursive scheme [39, 50]). Thus, it would have been natural for the 2900 schematology literature to contain a result of the form stated above. However, we were unable to find a paper 2901 with such a result; when procedures are allowed, the main interest seems to be in recursive procedures and 2902 how such programs compare with programs written in a language without procedure calls, but other features, 2903 such as arrays, stacks, or counters [17, 22]. 2904

The compression abilities of CFLOBDDs are based what might be called "multiplicative amplification": 2905 calls to procedures P and Q, when performed in sequence, result in a structure in which the number of 2906 L(matched)-paths is equal to the product of the numbers of L(matched)-paths through P and Q. Multiplicative 2907 amplification leads to the repeated squaring we see in counting the number of paths from the entry vertex to 2908 the (one) exit vertex of a no-distinction proto-CFLOBDD with *k* levels:

$$P(0) = 1$$
  $P(n+1) = P(n)^2$ 

A more powerful compression principle-again based on an "amplification" step repeated some number of times-is found in Mairson's rational reconstruction of a proof of Statman's [40]. As with CFLOBDDs, there are a finite number of stratification levels and no recursion, but instead of "multiplicative amplification," Mairson uses "powerset amplification." He is interested in representing all values of the stratified types defined by

$$\mathcal{D}_0 = \{ \text{true, false} \}$$
  $\mathcal{D}_n = powerset(D_{n-1}).$ 

2917 Mairson observes that one can use linked lists to represent the elements of each of the  $\mathcal{D}_i$ . To represent 2918 them concisely, he defines a powerset-combinator powerset that takes a list  $l_1$  as input, and returns a list  $l_2$ 2919 that contains the powerset of the elements of  $l_1$  (a simple exercise in functional programming). He can then 2920 represent  $\mathcal{D}_n$  with a  $\lambda$ -calculus term  $D_n$  that applies powerset *n* times to the list {true, false}. Considered as 2921 a member of the family of terms  $D_0, D_1 = \mathsf{powerset}(D_0), \dots, D_n = \mathsf{powerset}^n(D_0), \dots$ , the size of the term  $D_n$  is  $\Omega(n)$ . In contrast, the size of the set that is represented by  $D_n$  is described by the following recurrence 2922 relation: 2923

 $S(0) = 1 \qquad S(n+1) = 2^{S(n)},$ whose solution is non-elementary: S(n) is an exponential tower of 2s,  $2^{2^{2}}$ , of height *n*.

#### CONCLUSIONS 12

This paper described a new data structure-CFLOBDDs-for representing functions, matrices, relations, and 2929 other discrete structures. CFLOBDDs are a plug-compatible replacement for BDDs, and can represent Boolean 2930 functions in a more compressed fashion than BDDs-exponentially smaller in the best case-and, again in 2931 the best case, double-exponentially smaller than the size of a Boolean function's decision tree. Moreover, we 2932

2933 <sup>22</sup> Unfortunately, the aforementioned work with the 20,000-line program that had 2<sup>400,000</sup> paths (which is what prompted 2934 Melski and Reps to realize that they were facing double-exponential explosion) was carried out after their CC '99 paper had been published [44]. The latter paper states, incorrectly, "In the worst case, the number of paths through a program is 2935 exponential in the number of branch statements b ..." [44, §5]. (This kind of mistake seems to be common among authors 2936 working with structures that are DAG-like, but are really based on acyclic hyper-graphs: they erroneously think that they 2937 are dealing with DAGs and conclude that there is exponential explosion/compression, whereas the true state of affairs is 2938 that they have double-exponential explosion/compression. Examples are found in the literature on E-graphs [48, 67] and version-space algebras [25, 35, 51].) 2939

showed an inherently exponential separation between CFLOBDDs and ROBDDs: the CFLOBDD for a function*g* can be exponentially smaller than *any* ROBDD for *g*.

Our experiments compared the time and space usage of CFLOBDDs and BDDs on two types of benchmarks: (i) micro-benchmarks, and (ii) quantum-simulation benchmarks. We found that the improvement in scalability with CFLOBDDs can be quite dramatic. These results support the conclusion that, for at least some applications, CFLOBDDs provide a much more compressed representation of discrete structures than is possible with BDDs, thereby permitting much larger problem instances to be handled than heretofore.

# 13 ACKNOWLEDGMENTS

We thank Richard Lipton for the suggestion to apply CFLOBDDs to quantum simulation, Patrick Emonts for advice about the proper way to perform quantum-circuit simulation with tensor networks, and the referees for suggestions of how to clarify several items in the presentation.

The work was supported, in part, by a gift from Rajiv and Ritu Batra; by the John Simon Guggenheim Memorial Foundation; by Facebook under a Probability and Programming Research Award; by NSF under grants CCR-9986308 and CCF-2212559; by ONR under contracts N00014-00-1-0607 and N00014-19-1-2318; by the MDA under SBIR contract DASG60-01-P-0048 to GrammaTech, Inc., and by an S.N. Bose Scholarship to Meghana Aparna Sistla. Thomas Reps has an ownership interest in GrammaTech, Inc., which has licensed elements of the technology reported in this publication.

3088	A	DETAILS OF NOTATION FOR CFLOBDDS AND THEIR COMPONENTS
3089	A f	ew words are in order about the notation used in the pseudo-code:
3090		• A Java-like semantics is assumed. For example, an object or field that is declared to be of type
3091		InternalGrouping is really a pointer to a piece of heap-allocated storage. A variable of type
3092		InternalGrouping is declared and initialized to a new InternalGrouping object of level $k$ by the
3093		declaration
3094		<pre>InternalGrouping g = new InternalGrouping(k)</pre>
3095		• Procedures can return multiple objects by returning tuples of objects, where tupling is denoted by
3096		square brackets. For instance, if f is a procedure that returns a pair of ints—and, in particular, if f(3)
3097		returns a pair consisting of the values 4 and 5-then int variables a and b would be assigned 4 and 5 by
3098		the following initialized declaration:
3099		$int \times int [a,b] = f(3)$
3100		• The indices of array elements start at 1.
3101		• Arrays are allocated with an initial length (which is allowed to be 0); however, arrays are assumed to
3102		lengthen automatically to accommodate assignments at index positions beyond the current length.
3103		$\bullet$ We assume that a call on the constructor <code>InternalGrouping(k)</code> returns an <code>InternalGrouping</code> in
3104		which the members have been initialized as follows:
3105		level = k
3106		AConnection = NULL
3107		AReturnluple = NULL
3108		BConnections = new array[0] of Grouping
3109		BReturnTunles = new array[0] of ReturnTunle
3110		numberOfExits = 0
3111		Similarly, we assume that a call on the constructor CFLOBDD(g.vt) returns a CFLOBDD in which the
3112		members have been initialized as follows:
3113		grouping = g
3114		valueTuple = vt
3115		The class definitions of Alg. 4, as well as the algorithms for the core CFLOBDD operations make use of the
3110	foll	owing auxiliary classes:
2110		• A ReturnTuple is a finite tuple of positive integers.
3110		• A PairTuple is a sequence of ordered pairs.
3120		• A TripleTuple is a sequence of ordered triples.
3121		• A Value luple is a finite tuple of whatever values the multi-terminal CFLOBDD is defined over.
3122	В	PROOF OF THE LEXICOGRAPHIC-ORDER PROPOSITION
3123	Pro	<b>prosition 4.1</b> (Lexicographic-Order Proposition). Let $e_{X_{C}}$ be the sequence of exit vertices of proto-CFLOBDD
3124	С.	Let $ex_I$ be the sequence of exit vertices reached by traversing C on each possible Boolean-variable-to-
3125	Вос	lean-value assignment, generated in lexicographic order of assignments. Let s be the subsequence of $ex_L$ that
3126	reta	ains just the leftmost occurrences of members of $ex_L$ (arranged in order as they first appear in $ex_L$ ). Then $ex_C = s$ .
3127		
3128	Pro	of: We argue by induction over levels:
3129	D -	
3130	Баз	<i>case</i> : The proposition follows immediately for level-0 proto-CFLOBDDs.
3131	Ind	uction step: The induction hypothesis is that that the proposition holds for every level-k proto-CFLOBDD.
3132	1,1,0	Let C be an arbitrary level- $k+1$ proto-CFLOBDD, with s and $ex_C$ as defined above. Without loss of generality.
3133	we	will refer to the exit vertices by ordinal position; i.e., we will consider $ex_C$ to be the sequence $[1, 2,,  ex_C ]$ .
3134	Let	$C_A$ denote the A-connection of C, and let $C_{B_n}$ denote C's $n^{th}$ B-connection. Note that $C_A$ and each of the
3135	$C_{B_{r}}$	are level- <i>k</i> proto-CFLOBDDs, and hence, by the induction hypothesis, the proposition holds for them.
3136		

, Vol. 1, No. 1, Article . Publication date: December 2023.

65

We argue by contradiction: Suppose, for the sake of argument, that the proposition does not hold for *C*, and that *j* is the leftmost exit vertex in  $ex_C$  for which the proposition is violated (i.e.,  $s(j) \neq j$ ). Let *i* be the exit vertex that appears in the *j*<sup>th</sup> position of *s* (i.e., s(j) = i). It must be that j < i.

<sup>3140</sup> Let  $\alpha_j$  and  $\alpha_i$  be the earliest assignments in lexicographic order (denoted by  $\prec$ ) that lead to exit vertices *j* and *i*, respectively. Because *i* comes before *j* in *s*, it must be that  $\alpha_i \prec \alpha_j$ .

Let  $\alpha_j^1$  and  $\alpha_j^2$  denote the first and second halves of  $\alpha_j$ , respectively; let  $\alpha_i^1$  and  $\alpha_i^2$  denote the first and second halves of  $\alpha_i$ , respectively. Let + denote the concatentation of assignments (e.g.,  $\alpha_j = \alpha_i^1 + \alpha_i^2$ ).

3144 There are two cases to consider.

3145 Case 1:  $\alpha_i^1 = \alpha_j^1$  and  $\alpha_i^2 < \alpha_j^2$ .

Because  $\alpha_i^1 = \alpha_j^1$ , the first halves of the matched path followed during the interpretations of assignments  $\alpha_i$ and  $\alpha_j$  through  $C_A$  are identical, and bring us to some middle vertex, say *m*, of *C*; both paths then proceed through  $C_{B_m}$ . Let  $e_i$  and  $e_j$  be the two exit vertices of  $C_{B_m}$  reached by following matched paths during the interpretations of  $\alpha_i^2$  and  $\alpha_j^2$ , respectively. There are now two cases to consider:

Case 1.A: Suppose that  $e_i < e_j$  in  $C_{B_m}$  (see Fig. 19a). In this case, the return edges  $e_i \rightarrow i$  and  $e_j \rightarrow j$  "cross". By Structural Invariant 2b, this can only happen if

- There is a matched path corresponding to some assignment  $\beta^1$  through  $C_A$  that leads to a middle vertex h, where h < m.
- There is a matched path from *h* corresponding to some assignment  $\beta^2$  through  $C_{B_h}$  (where  $C_{B_h}$  could be  $C_{B_m}$ ).
  - There is a return edge from the exit vertex reached by  $\beta^2$  in  $C_{B_h}$  to exit vertex j of C.

In this case, by the induction hypothesis applied to  $C_A$ , and the fact that h < m, it must be the case that we can choose  $\beta^1$  so that  $\beta^1 < \alpha_j^1$ .

<sup>3159</sup> Consequently,  $\beta^1 + \beta^2 < \alpha_j^1 + \alpha_j^2$ , which contradicts the assumption that  $\alpha_j = \alpha_j^1 + \alpha_j^2$  is the least assignment <sup>3160</sup> in lexicographic order that leads to *j*.

<sup>3161</sup> *Case 1.B:* Suppose that  $e_j < e_i$  in  $C_{B_m}$  (see Fig. 19b). Because  $\alpha_i^2 < \alpha_j^2$ , the induction hypothesis applied <sup>3162</sup> to  $C_{B_m}$  implies that there must exist an assignment  $\gamma < \alpha_i^2 < \alpha_j^2$  that leads to  $e_j$ . In this case, we have <sup>3163</sup> that  $\alpha_j^1 + \gamma < \alpha_j^1 + \alpha_j^2$ , which again contradicts the assumption that  $\alpha_j = \alpha_j^1 + \alpha_j^2$  is the least assignment in <sup>3164</sup> lexicographic order that leads to *j*.

Case 2:  $\alpha_i^1 \prec \alpha_j^1$ .

Because  $\alpha_i^1 < \alpha_j^1$ , the first halves of the matched paths followed during the interpretations of assignments  $\alpha_i$  and  $\alpha_j$  through  $C_A$  bring us to two different middle vertices of C, say m and n, respectively. The two paths then proceed through  $C_{B_m}$  and  $C_{B_n}$  (where it could be the case that  $C_{B_m} = C_{B_n}$ ), and return to i and j, respectively, where j < i. Again, there are two cases to consider:

<sup>3170</sup> *Case 2.A*: Suppose that n < m (see Fig. 19c.) The argument is similar to Case 1.B above: By Structural <sup>3171</sup> Invariant 1, n < m means that the exit vertex reached by  $\alpha_j^1$  in  $C_A$  comes before the exit vertex reached by <sup>3172</sup>  $\alpha_i^1$  in  $C_A$ . By the induction hypothesis applied to  $C_A$ , there must exist an assignment  $\gamma < \alpha_i^1 < \alpha_j^1$  that leads <sup>3173</sup> to the exit vertex reached by  $\alpha_j^1$  in  $C_A$ . In this case, we have that  $\gamma + \alpha_j^2 < \alpha_j^1 + \alpha_j^2$ , which contradicts the <sup>3174</sup> assumption that  $\alpha_j = \alpha_j^1 + \alpha_j^2$  is the least assignment in lexicographic order that leads to *j*.

*Case 2.B:* Suppose that m < n (see Fig. 19d.) The argument is similar to Case 1.A above: By Structural Invariant 2, we can only have m < n and j < i if

- There is a matched path corresponding to some assignment  $\beta^1$  through  $C_A$  that leads to a middle vertex h, where h < m.
  - There is a matched path from *h* corresponding to some assignment  $\beta^2$  through  $C_{B_h}$  (where  $C_{B_h}$  could be  $C_{B_m}$  or  $C_{B_n}$ ).
    - There is a return edge from the exit vertex reached by  $\beta^2$  in  $C_{B_h}$  to exit vertex *j* of *C*.

In this case, by the induction hypothesis applied to  $C_A$ , and the fact that h < m < n, it must be the case that we can choose  $\beta^1$  so that  $\beta^1 < \alpha_i^1$ .

Consequently,  $\beta^1 + \beta^2 < \alpha_j^1 + \alpha_j^2$ , which contradicts the assumption that  $\alpha_j = \alpha_j^1 + \alpha_j^2$  is the least assignment in lexicographic order that leads to *j*.

In each of the cases above, we are able to derive a contradiction to the assumption that  $\alpha_j$  is the least assignment in lexicographic order that leads to *j*. Thus, the supposition that the proposition does not hold for *C* cannot be true.  $\Box$ 

## C PROOF OF THE CANONICITY OF CFLOBDDS

To show that CFLOBDDs are a canonical representation of functions over Boolean arguments, we must establish that three properties hold:

- (1) Every level-k CFLOBDD represents a decision tree with  $2^{2^k}$  leaves.
- (2) Every decision tree with  $2^{2^k}$  leaves is represented by some level-*k* CFLOBDD.
- (3) No decision tree with  $2^{2^k}$  leaves is represented by more than one level-*k* CFLOBDD (up to isomorphism).

As described earlier, following a matched path (of length  $O(2^k)$ ) from the level-k entry vertex of a level-k CFLOBDD to a final value provides an interpretation of a Boolean assignment on  $2^k$  variables. Thus, the CFLOBDD represents a decision tree with  $2^{2^k}$  leaves (and Obligation 1 is satisfied).

To show that Obligation 2 holds, we describe a recursive procedure for constructing a level-k CFLOBDD from an arbitrary decision tree with  $2^{2^k}$  leaves (i.e., of height  $2^k$ ). In essence, the construction shows how such a decision tree can be folded together to form a multi-terminal CFLOBDD.

The construction makes use of a set of auxiliary tables, one for each level, in which a unique representative for each class of equal proto-CFLOBDDs that arises is tabulated. We assume that the level-0 table is already seeded with a representative fork grouping and a representative don't-care grouping.

## CONSTRUCTION 1. [Decision Tree to Multi-Terminal CFLOBDD]

- (1) The leaves of the decision tree are partitioned into some number of equivalence classes e according to the values that label the leaves. The equivalence classes are numbered 1 to e according to the relative position of the first occurrence of a value in a left-to-right sweep over the leaves of the decision tree.
  - For Boolean-valued CFLOBDDs, when the procedure is applied at topmost level, there are at most two equivalence classes of leaves, for the values F and T. However, in general, when the procedure is applied recursively, more than two equivalence classes can arise.
  - For the general case of multi-terminal CFLOBDDs, the number of equivalence classes corresponds to the number of different values that label leaves of the decision tree.
- (2) (Base cases) If k = 0 and e = 1, construct a CFLOBDD consisting of the representative don't-care grouping, with a value tuple that binds the exit vertex to the value that labels both leaves of the decision tree.

If k = 0 and e = 2, construct a CFLOBDD consisting of the representative fork grouping, with a value tuple that binds the two exit vertices to the first and second values, respectively, that label the leaves of the decision tree.

If either condition applies, return the CFLOBDD so constructed as the result of this invocation; otherwise, continue on to the next step.

(3) Construct—via recursive applications of the procedure— $2^{2^{k-1}}$  level-k–1 multi-terminal CFLOBDDs for the  $2^{2^{k-1}}$  decision trees of height  $2^{k-1}$  in the lower half of the decision tree.

These are then partitioned into some number e' of equivalence classes of equal multi-terminal CFLOBDDs; a representative of each class is retained, and the others discarded. Each of the  $2^{2^{k-1}}$  "leaves" of the upper half of the decision tree is labeled with the appropriate equivalence-class representative for the subtree of the lower half that begins there. These representatives serve as the "values" on the leaves of the upper half of the decision tree when the construction process is applied recursively to the upper half in step 4.

- The equivalence-class representatives are also numbered 1 to e' according to the relative position of their first occurrence in a left-to-right sweep over the leaves of the upper half of the decision tree.
- (4) Construct—via a recursive application of the procedure—a level-k-1 multi-terminal CFLOBDD for the upper half of the decision tree.

3284	(5) Construct a level-k multi-terminal proto-CFLOBDD from the level-k-1 multi-terminal CFLOBDDs created
3285	in steps 3 and 4. The level-k grouping is constructed as follows:
3286	(a) The A-connection points to the proto-CFLOBDD of the object constructed in step 4.
3287	(b) The middle vertices correspond to the equivalence classes formed in step 3, in the order 1e'.
3288	(c) The A-connection return tuple is the identity map back to the middle vertices (i.e., the tuple $[1e']$ ).
3289	(d) The B-connections point to the proto-CFLOBDDs of the e' equivalence-class representatives constructed
3290	in step 3, in the order 1e'.
3291	(e) The exit vertices correspond to the initial equivalence classes described in step 1, in the order 1e.
3202	(f) The B-connection return tuples connect the exit vertices of the highest-level groupings of the equivalence-
2202	class representatives retained from step 3 to the exit vertices created in step 5e. In each of the equivalence-
3293	class representatives retained from step 3, the value tuple associates each exit vertex $x$ with some value $v$ ,
5294	where $1 \le v \le e$ ; x is now connected to the exit vertex created in step 5e that is associated with the same
3295	
3296	(g) Consult a table of all previously constructed level-k groupings to determine whether the grouping
3297	constructed by steps 5a-5f duplicate a previously constructed grouping. If so, discard the present grouping
3298	and switch to the previously constructed one; if not, enter the present grouping into the table.
3299	(6) Return a multi-terminal CFLOBDD created from the proto-CFLOBDD constructed in step 5 by attaching a
3300	value luple that connects (in order) the exit vertices of the proto-CFLOBDD to the e values from step 1.
3301	
3302	Fig. 20a shows the decision tree for the function $\lambda r_0 r_1 r_0 r_2$ ( $r_0 \oplus r_1$ ) $\lor$ ( $r_0 \wedge r_1 \wedge r_0$ ) Fig. 20b shows the
3303	state of things after step 3 of Construction 1. Note that even though the level-1 CFLOBDDs for the first three
3304	leaves of the top half of the decision tree have equal proto-CFLOBDDs <sup>23</sup> the leftmost proto-CFLOBDD maps
3305	its exit vertex to $F$ whereas the exit vertex is mapped to $T$ in the second and third proto-CFLOBDDs. Thus, in
3306	this case, the recursive call for the upper half of the decision tree (step 4) involves three equivalence classes of
3307	values.
3307	It is not hard to see that the structures created by Construction 1 obey the structural invariants that are
3308	required of CFLOBDDs:
3309	<ul> <li>Structural Invariant 1 holds because the A-connection return tunle created in step 5c of Construction 1</li> </ul>
3310	is the identity map.
3311	• Structural Invariant 2 holds because in steps 1 and 3 of Construction 1, the equivalence classes are
3312	numbered in increasing order according to the relative position of a value's first occurrence in a left-to-
3313	right sweep. In particular, this order is preserved in the exit vertices of each grouping constructed during
3314	an invocation of Construction 1 (cf. step 5f), which ensures that the "compact extension" property of
3315	Structural Invariant 2b holds at each level of recursion in Construction 1.
3316	• Structural Invariant 3 holds because Construction 1 reuses the representative don't-care grouping and
3317	the representative fork grouping in step 2, and checks for the construction of duplicate groupings—and
3318	hence duplicate proto-CFLOBDDs—in step 5g.
3319	• Structural Invariant 4 holds because of steps 3, 5d, and 5f. On recursive calls to Construction 1, step 3
3320	partitions the CFLOBDDs constructed for the lower half of the decision tree into equivalence classes of
3321	CFLOBDD values (i.e., taking into account both the proto-CFLOBDDs and the value tuples associated
3322	with their exit vertices). Therefore, in steps 5d and 5f, duplicate <i>B</i> -connection/return-tuple pairs can
3332	never arise.
3323	• Structural Invariant 5 holds because step 6 uses the proto-CFLOBDD constructed in step 5.
3324	• Structural Invariant 6 holds because step 1 of Construction 1 constructs equivalence classes of values
3325	(ordered in increasing order according to the relative position of a value's first occurrence in a left-to-
3326	right sweep over the leaves of the decision tree).
3327	Moreover, Construction 1 preserves interpretation under assignments: Suppose that $C_T$ is the level-k
3328	CFLOBDD constructed by Construction 1 for decision tree <i>T</i> ; it is easy to show by induction on <i>k</i> that for
3329	every assignment $\alpha$ on the 2 <sup>k</sup> Boolean variables $x_0, \ldots, x_{2k-1}$ , the value obtained from $C_T$ by following the
3330	······································
3331	<sup>23</sup> The equality of the proto-CFLOBDDs is detected in step 5g.

Fig. 21. (a) Decision tree for  $\lambda x_0 x_1 x_0$ ; (b) fully expanded form of the CFLOBDD; (c) CFLOBDD.

corresponding matched path from the entry vertex of  $C_T$ 's highest-level grouping is the same as the value obtained for  $\alpha$  from T. (The first half of  $\alpha$  is used to follow a path through the A-connection of  $C_T$ , which was constructed from the top half of T. The second half of  $\alpha$  is used to follow a path through one of the B-connections of  $C_T$ , which was constructed from an equivalence class of bottom-half subtrees of T; that equivalence class includes the subtree rooted at the vertex of T that is reached by following the first half of  $\alpha$ .) Thus, every decision tree with  $2^{2^k}$  leaves is represented by some level-k CFLOBDD in which meaning (interpretation under assignments) has been preserved; consequently, Obligation 2 is satisfied.

We now come to Obligation 3 (no decision tree with  $2^{2^k}$  leaves is represented by more than one level-*k* CFLOBDD). The way we prove this property is to define an unfolding process, called *Unfold*, that starts with a multi-terminal CFLOBDD and works in the opposite direction to Construction 1 to construct a decision tree; that is, *Unfold* (recursively) unfolds the *A*-connection, and then (recursively) unfolds each of the *B*-connections. For instance, for the example shown in Fig. 20, *Unfold* would proceed from Fig. 20c, to Fig. 20b, and then to the decision tree for the function  $\lambda x_0 x_1 x_2 x_3.(x_0 \oplus x_1) \lor (x_0 \land x_1 \land x_2)$  shown in Fig. 20a.

3410 Unfold also preserves interpretation under assignments: Suppose that  $T_C$  is the decision tree constructed 3411 by Unfold for level-k CFLOBDD C; it is easy to show by induction on k that for every assignment  $\alpha$  on the  $2^k$ Boolean variables  $x_0, \ldots, x_{2^{k-1}}$ , the value obtained from *C* by following the corresponding matched path from 3412 the entry vertex of C's highest-level grouping is the same as the value obtained for  $\alpha$  from T<sub>C</sub>. (The first half 3413 of  $\alpha$  is used to follow a path through the A-connection of C, which Unfold unfolds into the top half of  $T_C$ . The 3414 second half of  $\alpha$  is used to follow a path through one of the *B*-connections of *C*, which *Unfold* unfolds into 3415 one or more instances of bottom-half subtrees of  $T_C$ ; that set of bottom-half subtrees includes the subtree 3416 rooted at the vertex of T that is reached by following the first half of  $\alpha$ .) 3417

Obligation 3 is satisfied if we can show that, for every CFLOBDD *C*, Construction 1 applied to the decision tree produced by Unfold(C) yields a CFLOBDD that is isomorphic to *C*. To establish that this property holds, we will define two kinds of *traces*:

3420 • A Fold trace records the steps of Construction 1: 3421 - At step 1 of Construction 1, the decision tree is appended to the trace. 3422 - At the end of step 2 (if either of the conditions listed in step 2 holds), the level-0 CFLOBDD being 3423 returned is appended to the trace (and Construction 1 returns). 3424 - During step 3, the trace is extended according to the actions carried out by the folding process as it is 3425 applied recursively to each of the lower-half decision trees. (For purposes of settling Obligation 3, we 3426 will assume that the lower-half decision trees are processed by Construction 1 in *left-to-right* order.) 3427 - At the end of step 3, a hybrid decision-tree/CFLOBDD object (à la Fig. 20b) is appended to the trace. - During step 4, the trace is extended according to the actions carried out by the folding process as it is 3428 applied recursively to the upper half of the decision tree. 3429 3430

Fig. 22. The *Fold* trace generated by the application of Construction 1 to the decision tree shown in Fig. 21a to create the CFLOBDD shown in Fig. 21c.

Fig. 23. The *Unfold* trace generated by the application of *Unfold* to the CFLOBDD shown in Fig. 21c to create the decision tree shown in Fig. 21a.

3463	
3464	- At the end of step 6, the CFLOBDD being returned is appended to the trace.
3465	For instance, Fig. 22 shows the Fold trace generated by the application of Construction 1 to the decision
3466	tree shown in Fig. 21a to create the CFLOBDD shown in Fig. 21c.
3467	• An <i>Unfold trace</i> records the steps of <i>Unfold</i> ( <i>C</i> ):
3468	<ul> <li>CFLOBDD <i>C</i> is appended to the trace.</li> </ul>
3469	– If <i>C</i> is a level-0 CFLOBDD, then a binary tree of height 1—with the leaves labeled according to <i>C</i> 's
3470	value tuple—is appended to the trace (and the <i>Unfold</i> algorithm returns).
3471	- The trace is extended according to the actions carried out by Unfold as it is applied recursively to the
3472	<i>A</i> -connection of <i>C</i> .
2472	<ul> <li>A hybrid decision-tree/CFLOBDD object (à la Fig. 20b) is appended to the trace.</li> </ul>
34/3	- The trace is extended according to the actions carried out by Unfold as it is applied recursively to
3474	instances of B-connections of C. (For purposes of settling Obligation 3, we will assume that Unfold
3475	processes a separate instance of a B-connection for each leaf of the hybrid object's upper-half decision
3476	tree, and that the B-connections are processed in right-to-left order of the upper-half decision tree's
3477	leaves.)
3478	- Finally, the decision tree returned by <i>Unfold</i> is appended to the trace.
3479	

For instance, Fig. 23 shows the <i>Unfold</i> trace generated by the application of <i>Unfold</i> to the CFLOBDD shown in Fig. 21c to create the decision tree shown in Fig. 21a.
Note how the <i>Unfold</i> trace shown in Fig. 23 is the reversal of the <i>Fold</i> trace shown in Fig. 22. We now argue that this property holds generally. (Technically, the argument given below in Proposition C.1 shows that each element of an <i>Unfold</i> trace is <i>isomorphic</i> to the corresponding object in the <i>Fold</i> trace, which suffices to imply that that Obligation 3 is satisfied, in the sense that a decision tree is represented by exactly one isomorphism class of CFLOBDDs.)
PROPOSITION C.1. Suppose that C is a multi-terminal CFLOBDD, and that $Unfold(C)$ results in Unfold trace UT and decision tree $T_0$ . Let C' be the multi-terminal CFLOBDD produced by applying Construction 1 to $T_0$ , and FT be the Fold trace produced during this process. Then
<ul> <li>(i) FT is the reversal of UT.</li> <li>(ii) C and C' are isomorphic.</li> </ul>
<i>Proof:</i> Because $C'$ appears at the end of $FT$ , and $C$ appears at the beginning of $UT$ , clause (i) implies (ii). We show clause (i) by the following inductive argument:
<i>Base case</i> : The proposition is trivially true of level-0 CFLOBDDs. Given any pair of values $v_1$ and $v_2$ (such as $F$ and $T$ ), there are exactly four possible level-0 CFLOBDDs: two constructed using a don't-care grouping—one in which the exit vertex is mapped to $v_1$ , and one in which it is mapped to $v_2$ —and two constructed using a fork grouping—one in which the two exit vertices are mapped to $v_1$ and $v_2$ , respectively, and one in which they are mapped to $v_2$ and $v_1$ , respectively. These unfold to the four decision trees that have $2^{2^0} = 2$ leaves and leaf-labels drawn from $\{v_1, v_2\}$ , and the application of Construction 1 to these decision trees yields the same level-0 CFLOBDD that we started with. (See step 2 of Construction 1.) Consequently, the <i>Fold</i> trace <i>FT</i> and the <i>Unfold</i> trace <i>UT</i> are reversals of each other.
<i>Induction step</i> : The induction hypothesis is that the proposition holds for every level- $k$ multi-terminal CFLOBDD. We need to argue that the proposition extends to level- $k+1$ multi-terminal CFLOBDDs. First, note that the induction hypothesis implies that each decision tree with $2^{2^k}$ leaves is represented by exactly one level- $k$ CFLOBDD isomorphism class. We will refer to this as the <i>corollary to the induction hypothesis</i> . <i>Unfold</i> trace <i>UT</i> can be divided into five segments:
<ul> <li>(u1) <i>C</i> itself</li> <li>(u2) the <i>Unfold</i> trace for <i>C</i>'s <i>A</i>-connection</li> <li>(u3) a hybrid decision-tree/CFLOBDD object (call this object <i>D</i>)</li> <li>(u4) the <i>Unfold</i> trace for <i>C</i>'s <i>B</i>-connections</li> <li>(u5) <i>T</i><sub>0</sub>.</li> </ul>
<i>Fold</i> trace <i>FT</i> can also be divided into five segments:
(f1) $T_0$ (f2) the <i>Fold</i> trace for $T_0$ 's lower-half trees (f3) a hybrid decision-tree/CFLOBDD object (call this object $D'$ ) (f4) the <i>Fold</i> trace for $T_0$ 's upper-half (f5) $C'$ .
Because both (f1) and (u5) are $T_0$ , (u5) is obviously equal to (f1). Our goal, therefore, is to show that
<ul> <li>(u2) is the reversal of (f4);</li> <li>(u3) is equal to (f3);</li> <li>(u4) is the reversal of (f2); and</li> <li>(u1) is equal to (f5).</li> </ul>

Meghana Aparna Sistla, Swarat Chaudhuri, and Thomas Reps

, Vol. 1, No. 1, Article . Publication date: December 2023.
(u3) is equal to (f3) Consider the hybrid decision-tree/CFLOBDD object D obtained after Unfold has finished 3529 unfolding C's A-connection.<sup>24</sup> The upper part of D (the decision-tree part) came from the recursive 3530 invocation of Unfold, which produced a decision tree for the first half of the Boolean variables, in which 3531 each leaf is labeled with the index of a middle vertex from the level-k+1 grouping of C (e.g., see Fig. 20b). 3532 As a consequence of Prop. 4.1, together with the fact that Unfold preserves interpretation under 3533 assignments, the relative position of the first occurrence of a label in a left-to-right sweep over the 3534 leaves of this decision tree reflects the order of the level-k+1 grouping's middle vertices.<sup>25</sup> However, 3535 each middle vertex has an associated B-connection, and by Structural Invariants 2, 4, and 6, the middle 3536 vertices can be thought of as representatives for a set of pairwise non-equal CFLOBDDs (that themselves 3537 represent lower-half decision trees). 3538 Fold trace FT also has a hybrid decision-tree/CFLOBDD object, namely D'. The crucial point is that 3539 the action of partitioning  $T_0$ 's lower-half CFLOBDDs that is carried out in step 3 of Construction 1 also results in a labeling of each leaf of the upper-half's decision tree with a representative of an equivalence 3540 class of CFLOBDDs that represent the lower half of the decision tree starting at that point. 3541 By the corollary to the induction hypothesis, the  $2^{2^k}$  bottom-half trees of  $T_0$  are represented uniquely 3542 (up to isomorphism) by the respective CFLOBDDs in D'. Similarly, by the corollary to the induction 3543 hypothesis, the  $2^{2^k}$  CFLOBDDs used as labels in D represent uniquely (up to isomorphism) the respective 3544 bottom-half trees of  $T_0$ . Thus, the labelings on D and D' must be isomorphic. 3545 (u2) is the reversal of (f4); (u4) is the reversal of (f2) Given the observation that D and D' are isomorphic, 3546 these properties follow in a straightforward fashion from the inductive hypothesis (applied to the 3547 A-connection and the B-connections of C). 3548 (u1) is equal to (f5) Because (u2) is the reversal of (f4) and (u4) is the reversal of (f2), we know that the 3549 level-k proto-CFLOBDDs out of which the level-k+1 grouping of C' is constructed are isomorphic to 3550 the respective level-k proto-CFLOBDDs that make up the A-connection and B-connections of C. 3551 We already argued that steps 5 and 6 of Construction 1 lead to CFLOBDDs that obey the six structural 3552 invariants required of CFLOBDDs. Moreover, there is only one way for Construction 1 to construct the 3553 level-k+1 grouping of C' so that Structural Invariants 2, 3, and 4 are satisfied. Therefore, C is isomorphic to C'. 3554 3555 Consequently, *FT* is the reversal of *UT*, as was to be shown.  $\Box$ 3556 In summary, we have now shown that Obligations 1, 2, and 3 are all satisifed. These properties imply that, 3557 for a given ordering of Boolean variables, if two level-k CFLOBDDs  $C_1$  and  $C_2$  represent the same decision tree 3558 with  $2^{2^k}$  leaves, then  $C_1$  and  $C_2$  are isomorphic—i.e., CFLOBDDs are a canonical representation of functions 3559 over Boolean arguments: 3560 **Theorem 4.3.** (CANONICITY). If  $C_1$  and  $C_2$  are level-k CFLOBDDs for the same Boolean function over  $2^k$ 3561 Boolean variables, and  $C_1$  and  $C_2$  use the same variable ordering, then  $C_1$  and  $C_2$  are isomorphic. 3562 3563 3564 3565

3577

 <sup>&</sup>lt;sup>24</sup>The *A*-connection is actually a proto-CFLOBDD, whereas *Unfold* works on multi-terminal CFLOBDDs. However, the
A-connection return tuple (with the indices of the middle vertices as the value space) serves as the value tuple whenever we
wish to consider the *A*-connection as a multi-terminal CFLOBDD.

<sup>&</sup>lt;sup>25</sup>This step is where the argument would break down if we attempt to apply the same argument to Fig. 8a: In that case, the labels on the leaves of *D*, in left-to-right order, would be 2 and 1—whereas the sequence of middle vertices in Fig. 8a is [1,2].
